Most things can be modeled, at worst as an extrapolated lookup table built from empirical measurements. If it can be modeled, then Reg's program can be made more accurate. Isn't that what we want here, better, more accurate tools?

Hello all,

I have the Hustler coils but, I'm missing the 54" mast they mount on. The coils I'm talking about are the old white coils for 10-15-20-40-80 meters that were kinda popular 10 or 15 years ago. I'd be more than happy with the solid mast but, a folding one is acceptable as well.

Does anyone have one of these laying around they want to part with??

OR, maybe someone has come up with a work around for the mast. I'm trying to mount these on the roll bar on my pickup truck so height is not a problem.. I can only get them down to a 3:1 swr though.. Any ideas??

Drop me an e-mail and we'll work out the $$'s.

Hello,

I running an off-center-fed inverted V with ladder line and a tuner.
One leg about 80 feet, the other about 40. It works pretty good
on 20,40, and 80 meters -- I haven't tried any other bands.

I've seen similar antenna descriptions in QST or one of the antenna
compendiums
One caught my eye which used 4-conductor flat cable - each conductor cut for
separate bands.
I think the cable was rotor control cable -
but it would be interesting to see how something like 14/3wg uf cable would
work out
I just use a G5RV and a tuner

The meter reading matches what I would have expected to see. I did measure
another mag mount and got around 150pf, BUT that one was missing the
aluminium foil sheet that should cover the bottom.

>
> However, this is one component you have not measured, and admittedly
> so. It also begs discussing other sources of failure that go

> fraught with large scale error.

The capacitance meter used is not based on using frequency. Typicaly they
will use a constant current source and measure the time to reach a fixed
voltage on the capacitor. Since using a constant current source results in a
linear rate of charge the time required to reach a fixed voltage is directly
related to the capacitance. Using this method there are NO frequency effects
to screw up the reading.

You should know better. Many many antenna maufactures take advantange of the significant resistance of the loading coils they use to raise the feed point impedance to something near 50 ohms. A very short, electricaly, antenna may ony exibit several ohms of impedance at the operating frequency. I've even used my RF impedance bridge to confirm it. If the loading coil in series with an antenna can raise the feed point impedance, then a very losy capacitor in series can do the same.

I think everybody knows that antennas have standing waves on them, but that doesn't have a thing to do with coupling the sheild of the coax to a ground plane, which by the way is the main point which you haven't addressed.

And the manufactures of those real stubby mag-mount antennas do just that effectively by using real high loss base loading coils. But don't tell the unsuspecting CBers that.

> As such, I will assign it a plate separation distance of half the
> overall cable O.D. or 0.105". Plugging and chugging through the
> standard formulas results in several hundred pF.

Two problems. One the RF is confined to the area between the shield and the center wire in the coax. Second if it isn't then you have unbalanced currents flowing on the coax thus making the coax a part of the radiating system, not to mention the fact that the RF current at the antenna end of the coax isn't the same as at the transmitter end. And that has to be the case because what current flows through the capacitance to ground along the length of the coax can't exit at the end. Think about what your SWR meter would make of a situation like that.

Capacitive coupling to the body of the car is required where direct grounding is not possible. If you don't believe it then stick a known mag-mount antenna on a car, run the coax away from all the sheet metal, and check the match. Then disconnect the shield inside of the base and see what happens. Then for further proof directly ground one end of a capacitor, in the neighborhood of the values discussed here, then connect the shield of the coax to the free end and check your match, Remember to keep the leads real short to prevent the extra wire length from detuning the antenna too much. That should be sufficient to make my point.

Frank I design Induction Heating power supplies for a living, including RF. I'm probably more aware of capacitor characteristics that you may think. I've had custom capacitors designed by another company in our group specifically for applications in some of our equipment based on my specifications. I've tested capacitors to failure under all manner of conditions etc.

> Why are mica, air and vacuum caps sometimes preferred for RF

Little to no dielectric heating in the case of mica and the vacuum type is used where you need to handle very high voltages without using very high plate to plate spacing in an air dielectric type. Also some of those air dielectric types burn up the ball bearings from arcing due to poor contact, where used, that support the shaft. Something to watch out for when shopping for used parts.

> over ceramic?

The ceramic has higher losses. I've blown enough of them up to know. You also have to watch out how much current those little disk jobs carry. The plating on the ceramic can lead to unexpected I^2 R losses on them too.

>Why not just use electrolytics?

Unless they are specially designed they don't have good high frequency characteristics, high ESR, and they typically can't handle high levels of ripple, AC, current. Somebody had us design a power supply doing 5KW using a single phase supply, I had to use a load of electrolytics to keep the ripple current below the cap's ratings, which wasn't much.

> Of course you know the

If I wanted to know the impedance yes. But if all I want is the capacitance without all of the stray inductance, capacitor loses etc. lumped in the

answer is no.

I though I made it clear, I don't care what the ESR happens to be. I'm only
interested in the capacitance value.

>
>
> > Capacitive coupling to the body of the car is required,
>
>
> That's just flat-out wrong.

Frank I'm just going to call this thread quits. I'm satisfied with how the
mag-mount antenna works. If you don't agree then that's for you to deal
with. What I described matches what I have read, makes sense with theory,
matches experiments I've done some time back etc. I think you need to spend
more time researching the subject. Just remember that at one time some
people said the earth was flat, oh well.

Hi Tom,

Taking it on my word is untraceable and merely fostering the
perpetuation of Reggie's Old Wive's Tale.

>I would want to know what is different about the 3 "identical"
> soils that aren't "identical".

The soils found in Quantico Maryland, Urbana Illinois, and Manhattan
Kansas are all identical in composition, and yet span nearly 10:1 in
conductivity.

>And the 3 unidentical "identical" soils.

The soils found in Culbertson Montana, Manhattan Kansas, and Fargo
North Dakota all have identical conductivity, and yet are spread out
in wildly diverging soil compositions.

>There must be something(s) that is(are) quantifiable, or they
>wouldn't have different responses. Duh.

What would you suggest it is about Reggie's software that
differentiates it across these 5 samples? Ask for more if you wish,
I've got roughly 50 across the United States, and I could probably
pull in another couple dozen from around the world.

As I said, the silence from Reggie on this topic speaks for itself.
England is a very, very small data set to forecast foreign ground
characteristics. His software may be suitable for his garden, but
across this continent it would require far more variables than those
offered. Soil is not that simple and it is largely beyond the
capacity of any individual here to characterize short of simply
burying a monopole and abstracting the loss (but that doesn't give you
any numbers to plug into the program, does it?).

Tom, why don't you offer us what your soil characteristics are, and
what numbers you would plug in? This simply proves the software
caveat: GIGO.

Sorry Richard, but I'm sure you can find a better adjective than "identical" to describe soils which react differently to resistance and impedance measurements. Such is an impossibility. As Tom said, something which is clearly quantifiable is different in order to produce drastically different resistance and impedance measurements. You have a circular argument that must be restated in order to be considered.

> The soils found in Culbertson Montana, Manhattan Kansas, and Fargo
> North Dakota all have identical conductivity, and yet are spread out
> in wildly diverging soil compositions.

Now this is a more common condition that could be said about several materials. It is possible to have different materials display very "similar" (for our purposes) resistance and impedance.

Even without testing for specific conductivity, average soil can still be considered to fall within a range that is useful for earthing ground system (and then why not radials?) planning purposes. I don't see why a software program could not offer a few ranges of conductivity that would fit 99% of all soil conductivity, no matter what the soil composition. We could really care less what the composition is as long as it offers good earthing or radial conductivity, right? Adding Bentonite would bring a low conductivity to a known standard. It would have this result in any soil anywhere in the world. Just my thoughts, as I don't believe you intended to make "soil" the issue, just it's differing conductivity - which isn't really all that different at given RH.

Best regards,

Jack Painter

Back in the 50's, Dad used an antenna he called a "Windom" It had ladder line feed and I 'think' it was off-center fed, but can't be sure. I'm surprised off-center feed isn't used more. It gets you away from feeding two ends of multiple half waves.

If you get "iron in the sky" and you get power into it, that's all you need....Pretty much.

So you disagree with this quote from:

http://www.keelynet.com/spider/b-114e.htm

"If frequencies of the generators are equal, then any transfer
of energy along the wire is out of the question, ..."

> Besides, two
> independently modulated waveforms can hardly be considered 'phase
> coherent'.

More than just the modulation energy is being transferred.
The carrier frequencies of the two signal generators are
phased-locked and the average amplitudes are identical.
The standing waves have a zero magnitude every 1/2WL. The
power dissipated in the circulator load is equal to the
power output from the opposite generator, even without any
modulation. How does that energy get past the zero magnitude
points of the standing waves?

==========

The error in the HTML code in the program's filename, uploaded wth the program to my website, was corrected within 2 or 3 hours. Replacing a single upper case character "R" by a lower case "r" was all that was needed. No permanent harm done.

My real error was in NOT checking it was possible to download the program myself before advertising the fact on newsgroups that a new program was available. Very remiss of me!

Source record: 91278

Last night I put up my new home-brew Off Center Fed antenna.

It's around 50 feet up, 135 feet in total length. There is a small section, ~30 feet that hangs down from the long end, due to lack of distance between trees.

Initial SWR readings are acceptable on all bands, but I'll be doing some trimming to see if I can't nudge them down a little more.

I haven't transmitted yet, save for some low power checks on each band, and a 100 watt power check on the band with the worst SWR to see that the PA amp didn't fold back. All fine there.

My question is, is there any good trick to the end with the "hangy down part"?

Initially, I have run the wire thorough the insulator, and Ty-wrapped the outgoing wire to the incoming one, then let it drop. Or should I run the wire to the insulator in the normal way, then attach the tail with solder? I'd prefer to keep the wire in one piece if possible.

Finally, is there any advantage to putting an insulator on the end of the tail and suspending that up in another tree? In my case, it would be at about a 90 degree angle to the main part of the dipole. I'm certain in principle it is, but is there likely to be a practical effect?

Identical is what identical is. This may be circular, but it is not
inconsistent. I suggest you re-read my premise and note the
distinctions of what identities are being discussed and dismiss Tom's
short hand of the original statement.

>> The soils found in Culbertson Montana, Manhattan Kansas, and Fargo
>> North Dakota all have identical conductivity, and yet are spread out
>> in wildly diverging soil compositions.
>
>Now this is a more common condition that could be said about several
>materials. It is possible to have different materials display very "similar"
>(for our purposes) resistance and impedance.

As I offered Tom: then what composes those outstanding characteristics
that distinguish them (and that are not part of this "program") to
render an useful solution? I am merely responding within the context
of what has been discussed here. If there is any paradox, it is
certainly not my fault - look to the source.

>Even without testing for specific conductivity, average soil can still be
>considered to fall within a range that is useful for earthing ground system

Average soil? I said nothing of averages. By this term's inclusion
it further mystifies the process and reveals nothing to a particular
solution. In fact, I expect none here can define an "average" soil.
I note that Reggie can respond to an HTML error, but is consistently
quiet in regard to these characteristics. [He doesn't know either.]

>(and then why not radials?) planning purposes. I don't see why a software
>program could not offer a few ranges of conductivity that would fit 99% of
>all soil conductivity, no matter what the soil composition.

What are your particular ranges and numerical entries such that you
would have a useful employment of this program?

This discussion of averages and dismissal of soil composition merely
demonstrates the program's total uselessness - a silent patronization
of Reggie's program. I am merely blunt about it.

The fact that this all devolves to the common advice of "lay down a
dozen radials, choose as much length as you feel good about" renders
the notion of seeking THE SAME solution through software is as
remarkable as using an old fashion Magic 8-Ball (which would at least
include honest answers such as "unknown at this time, ask again").

>We could really
>care less what the composition is as long as it offers good earthing or
>radial conductivity, right?

This reveals the ignorance of soil and its characteristics (which
includes conductivity) in the first place. There are probably only
two people in this group who could name the soil in their back yard -
Me and Reggie - and Reggie ain't gonna tell you no how, no way. ;-)

>Adding Bentonite would bring a low conductivity
>to a known standard. It would have this result in any soil anywhere in the
>world.

How many tons? See, this is the staple of ignorance that orbits this
discussion. The discussion is stuck in vague generalities (I have yet
to see anyone discuss how they ACTUALLY put the program to use - dare
I ask if any of you downloaded this shelf-ware?).

This goes to the heart and soul of Reggie's denouncement of software
users as a bunch of mindless fools barely capable of reading and
hardly numerically literate enough to enter a number with more than 2
digits. He would thump the tub that the Sewer Rats of Rio could
exercise their better understanding of the first principles such that
they would fleece such idiots in a mental showdown.

We get grandiloquent and gushing fond remembrances of British
Luminaries of science and how NUMBERS are the soul of discussion, not
trivial generalizations that bleat on into fantasy physics. Reggie
loves this kind of flag waving, and yet he is not incuriously absent
in this discussion. I enjoy the irony of his condescension of his
users - especially when they run to hug this reprobate.

> Just my thoughts, as I don't believe you intended to make "soil" the
>issue, just it's differing conductivity - which isn't really all that
>different at given RH.

But there you are wrong. I am fully prepared to discuss the RF nature
of soil, and I have in the past as the archives will reveal. You may

be right in the sense that no one really cares (and let's not forget to include the Troll Master himself) as evidenced by both so little discussion of specifics, and absolutely no sense of personal usage of the details.

Really, this is a case that there is literally NOTHING you can do about it. Knowing, for many, just doesn't matter. However, pretending is enough for some, and Old Wive's Tales reduced to software makes the rest feel like academicians, engineers and savants.

However, Jack, you did make one remarkable (and to this day and era - UNIQUE) contribution that even Reggie has not recognized. I will leave it as an exercise to all to see if they can spot it in your text above.

I won't hold my breath however. :-)

I doubt it. If you had such experience then you would know that
frequency plays an essential role in the application of any capacitor.

>> Why are mica, air and vacuum caps sometimes preferred for RF
>
>Little to no dielectric heating in the case of mica and the vacuum type is

See below.

> Also some of those air
>dielectric types burn up the ball bearings from arcing due to poor contact,
>where used, that support the shaft. Something to watch out for when shopping
>for used parts.

I've never seen anything of the sort since almost all air variables
are built with a type of grounding brush to the shaft, usually located
at both ends, and at the shields used to seperate the sections if it's
a multi-section cap. Ball bearings have never been relied upon as the
sole electrical connection to the shaft since they are usually coated
with some sort of non-conductive lubricant. If you had any of the
experience you claim you would have known that, too.

>> over ceramic?
>
>The ceramic has higher losses. I've blown enough of them up to know. You
>also have to watch out how much current those little disk jobs carry. The
>plating on the ceramic can lead to unexpected I^2 R losses on them too.

You missed the question. Regardless, the answer is because air, vacuum
and mica capacitors have a much higher Q at higher frequencies than
ceramic caps. IOW, with increasing frequency, the effective resistance
of the capacitor is higher for ceramic than for air, vacuum or mica
caps, the reactance being equal. Every dielectric will have a Q/f
curve. But that's only -one- of the reasons frequency is important for
testing. Others include dielectric conductivity (g increases with
increasing frequency), dielectric absorption, hysteresis, inductive
reactance, etc. Very few materials show the dielectric characteristics
that would make them suitable for RF capacitors, and I don't think
automobile paint is on that list.

>>Why not just use electrolytics?

The pure capacitance, or the "zero-frequency" value, is academic and
has no practical significance. Again, this is something you would know
if you had the experience you claim.

>> > About the ESR, equivalent

>I though I made it clear, I don't care what the ESR happens to be. I'm only
>interested in the capacitance value.

If you don't care about the ESR then you don't care about the
practicality of the mag-mount base as an RF ground since ESR is an
unavoidable confound in that or any other capacitance.

>> > Capacitive coupling to the body of the car is required,
>>
>>

>matches experiments I've done some time back etc. I think you need to spend
>more time researching the subject. Just remember that at one time some
>people said the earth was flat, oh well.

I suggested you perform the experiment as I did. It eliminates all
relevant confounds and gives an unextrapolated picture of how a
mag-mount base works. On the suggestion of another poster I have done
a second experiment which supports my conclusions, and also validites
the results of my first experiment. You have refused to do the
experiment, you have no justification to dispute it, and you are
demonstrating that your education and experience in the matter is not
even close to what you claim. So if you want to drop the thread then
that's probably a wise decision for you to make.

When you subtract overhead and benefits, that's is about 1/2. $65 is about right; maybe as high as $85-95 in some areas of the country--but probably not Chicago, whear the COL is lower than some other places.. That's my opinion, anyway.

In the right place, half that (65K) is close to what very good clerks are paid. Careful not to compare salary with cost (sal. + benefits + whatever). A consultant has to work for more than cost since he isn't working all year...then there's what the market/client will bear. This can very LOTS! There is clearly the haves an have nots.

Yea, OK on the $165 comment. Doing the math with 2080 hours per year, this is about correct. $135k, including all benefits/costs, is close to what it costs to support one very experienced Engineer in the corp world.
In the mid west, experienced Engineers (I have connections with) are in the $85-100K/yr range, but this is ONLY salary. Real hot shots are in the $115K+ range. What little 'special' work I have done can't really be called consulting, but I got about that on an hourly basis. They really have to want your skills and have the $$.

Sure, there are lots of people who would gladly work for $60k. Then again, there are lots of people who would b glad *2* work. Lot of us are watching our backs.

Why not?

If there are gigs out there, many do work all year long--save for reasonable vacation. I know several.

The going rate is just not in the $100/hr range in the midwest. That's pushing it in the east, too.

Source record: 91291

I have just bought a second hand Echostar AD-3000IP satellite receiver.
It is connected by a 2 pin power lead (no earth) to UK domestic 240V supply,
but emits strong modulated tones at AM frequencies centered on 1400KHz, even
when the unit is in standby mode.

Unfortunately this RFI is also rich in harmonics and can be heard at
2800KHz, 5600KHz etc all the way up to 21MHz. What is the best way of
suppressing this RFI?

As far as I can tell the RFI is airborne though I may try a ferrite bead on
the power lead.
The unit sits on a shelf in a small TV cabinet, and I may even try making a
faraday cage from aluminium cooking foil and connecting this to earth also.

Look forward to hear further ideas/solutions. TIA

Nope. That's not it. I've said the same thing all along. What makes
me angry is when out of the blue you come on here and start
mischaracterizing what I've said. You bring up some nutcase website,
and then try to saddle me with it.

> It is a simple yes/no question. A simple yes/no answer would

you might try 3 things
1. try reversing the plug first if possible - might work if other prong is
=to ground
(unplug, turn it around and replug)
2. if RFI is still there - replace the power cord with 3-prong - and ground
the case.
or
3. unplug it, remove the cover, and pummel with a hammer

I quote -

"I can show you three identical soils that are vastly different in RF
response."

So now they aren't identical. Which is what you originally said they
were. Which is it? Identical or not?

> His software may be suitable for his garden, but
> across this continent it would require far more variables than those
> offered. Soil is not that simple and it is largely beyond the
> capacity of any individual here to characterize short of simply
> burying a monopole and abstracting the loss (but that doesn't give you
> any numbers to plug into the program, does it?).

And I said -

"Most things can be modeled, at worst as an extrapolated lookup table
built from empirical measurements. If it can be modeled, then Reg's
program can be made more accurate. Isn't that what we want here,
better, more accurate tools?"

Which says, in simpler terms so you can't miss this time, maybe he could
make a better version with some intelligent feedback instead of you just
ripping him.

And you will probably again try to obfuscate, but don't expect any more
responses; as Roy said a while ago, I'm not playing the "last man
pissing wins" game either.

1480. Sometimes a light bulb just goes "on".... duuuuuuhhhhh

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-06 23:50:33 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <2nijpqF1c9ppU1@uni-berlin.de>
Source record: 91301

I moved from Wichita, KS to Aurora, CO (Denver area) a year ago.

In KS I was in a 1 story apartment but had a very ham friendly
landlord. I had a GAP Titan, a Comet GP-15, a 2m/440 vertical
and 4 el on 6, 13 el on 2 and 22 el on 440. Things were nice.

Then I moved to Denver. I picked the top floor of a 3 story aptartment
building, facing away from the mountains (NE corner apt.). I wrapped
a 153's dipole made from 22 g clear insulated wire around the building
for HF, put a 6m inverted V in the east window and plonked my MFJ
"Super High Gain" 2m/440 mag mount on the in the wall A/C unit, which
was just below the north window. Not a stellar setup but I could hit
any repeater within 25 miles and I was equal to a 20w mobile on HF.

After a year of no noise, no TVI, no damages, no cops, no parties and
paying the rent on the 1st every month I finally asked the landlord if
I could erect antennas on the roof. I explained that I always put up
antennas in such a way as they could later be removed with *very* little
if any evidence that they had been there.

He said OK but no higher than 10 feet above the roof and no holes.

I put up a 10 foot mast on a vent pipe mount, holding up a Van Gorden
134' "All Bander" antenna but left the other antennas stay put.

Duuuuuuuhhhh....

This morning it hits me - I've got a closet full of coax not being used!

1st, I moved (as an experiment) the 2m/440 mag mount from indoors
on the A/C unit to on the roof. I only had to add 4' of coax and on the
edge of the roof is steel flashing - perfect for the mag mount! Now I'm
hitting repeaters 65 miles away with 5w that I couldn't hit with 50 before
and I was recieving at S3-S4 levels. Full scale of course, now.

Then, I got more ideas - I took out my old RS mag mount CB ant (the
best loaded version they ever made - cost $57 - now cut for 10m) and
put it on the roof the same way. It's 18' of stock coax reached just fine.

Then came the 6 meter antenna - I grabbed a 50' prefab RS RG58 coax
piece and went to the roof with tape, knife, zip ties, rope, etc....

30 minutes later I had secured it as an inverted V to the 10' mast. I had
to re-tune it - it was cut for 50.2 but in the clear it resonated at 53.1!
I had to add like 6" of wire to each leg. Man - I thought all the Denver
area 6m repeaters were offline....NOT! 53.050 is up! Can't wait till
a band opening to see how this 6m ant works now.

So, I pulled my head out of $%^$^% and used the equipment on hand.
I now have antennas for 80-6, 11-10, 6, 2 & 70cm all up in the clear
and that also means no antennas (RF) in the shack. Nice.

I'd put a better coax on the 2m/440 ant but it's only 18.2' long so even
changing from RG58 to LMR400 probably wouldn't make sense. Heck
- it figures out to only 1.3db difference @ 460 mhz. Nah - not worth it I
was planning on spending $200 to put up a Diamond X50 on a 5' mast
fed with 50' of LMR400 but I don't think so now - I just don't think
it would make a difference as I'm hitting all the repeaters within 60 miles
on 5w now. So, that's out.

I do worry about the 68+' of RG58 I'm running to the 6m inverted V.
Loosing 2.2 db on that run @ 52 mhz. Changing to LMR400DB would
cut that to 0.6db, gaining 1.6db. Hmmmmm. Maybe. What I need is
a omnidirectional horizontaly polarized economical gain 6m antenna.

Anybody got ideas? After today's improvements, I want more!

Ken KG0WX

If its still there. Second the cheap recover type air variables use them,
and some people try to save a few bucks by pulling some of the plates out to
increase the air gap for higher voltage applications not understanding what
they are doing.

Dah, that's what I said Frank in different words about losses. The vacuum
variable is used for very high voltage ablications just like the vacuum RF
relays, no air no arcing. Nobody is going to the expense of using a vacuum
variable where an air job would work. At high voltages the required spacing
between the plates becomes so high that even a small valued cap is rather
large, so they use the vacuum variable to save space, but only if the
cost-space considerations make sense. You typicaly see them used in some
tuners because of the very high voltges that are developed to achive the
match.

> Every dielectric will have a Q/f
> curve.

I've seen the curves Frank. They don't have anything to do with the pure
capacitance of the device. And that's the point. You keep trying to very

unnecessarily complicate things by dragging in issues that have nothing to do with measuring capacitance exclusive of other issues. If you can't figure out that what you're measuring with a Z-bridge is a combination of capacitance, stray inductance with non-ideal effects from skin resistance thrown in, and the differenced between them circuit wise, it's apparent I'm not going to educate you any time soon. So like I said I'm not going to waste my time further on this thread.

No, that's not the point. The point is whether a mag-mount makes an
effective ground coupling via capacitance from the base to the vehicle
body. The fact is that it doesn't. And no matter how many indirect
measurements you make or variables you present in defense of your
opinion, you can't substitute them for a direct measurement at the
operating frequency.

> You keep trying to very
>unnecessarily complicate things by dragging in issues that have nothing to

I measured the impedance because the antenna and coax don't see "pure
capacitance". And I don't see how using the practical and real-world
value of impedance can "unnecessarily complicate things" because those
other issues are not only necessary, but unavoidable in practical use.
And a mag-mount is most definitely a practical use. Or maybe you would
like to explain why the inductive reactance and effective resistance
are 'unnecessary complications' with this or any other capacitor?

From my research I've found indications that radial length beyond a quarter wavelength is indeed significant out to about two wavelengths.

Ken,
You might look at the PAR Omniangle OA-50 which sells at AES for $70.
It is not a 'gain' antenna per se, but offers a very good omni pattern
and is more economical than the other 6 meter loops on the market. If
you want gain you could stack a couple of them. To get gain, you have
to compromise on the 'economical' criteria as loops tend to show
'about' the same gain as a dipole, however the cost of two loops is
less than one beam and a rotor.

While I do not own any PAR products (weren't available when I got my
AEA Halo or I would've gotten the omniangle!) they are well reviewed
in terms of performing as stated and quality of construction. Also, I
have communicated with Dale Parfitt, the man behind PAR, through both
the newsgroup and a few e-mails and have found him to be both
knowledgeable and a decent guy.

Good luck & hope to hear you on 6!

None of it makes any difference electrically. If the element conducts
any which way you build the "tail" and solder it yer done. The rest of
it involves common sense mechanical integrity/reliability sorts of
considerations.

> Finally, is there any advantage to putting an insulator on the end of

You won't know until you try it and neither will anybody else. WRT to
"practical effects" use an end insulator as a handy interface between
the hot end of the tail and some rope and hoist the end of the tail up
to somewhere away from the lawn mower and the kids.

You need to put lots of ferrite on both the AC cable AND the coax to the dish. Just because it is coax doesn't mean it can't act as an antenna at HF. In fact, disconnect the coax and see if the RFI doesn't drop significantly.

Hi OM,

Are you located near South Charleston? The soil in your region is a
Silty Loam. In comparison to Manhattan Kansas, which is 4 times more
conductive (probably a good indicator of your longer radials
effectivity), the soil characteristics (that pesky permittivity, no
one has a clue to guess) are identical. You could be worse off in
conductivity in Pendleton Oregon, but you would not be able to tell
the difference in the soil.

Three identical soils (ALL silty loams), three totally different
characteristics. Anyone try Reggie's program to figure out why? Or
is this a situation where you have to know the answer to find the
solution? ;-)

Thanks, for the tip, Howard!

After reading the general PAR and the OA-50 reviews on Eham, I'm
convinced it's the way to go! Universal Radio has them cheap ($68) - I
think I'll go for the gusto (It's only money) and order the stacking kit, 2
OA-50's and some LMR400 coax to feed them. At 35' above ground
level with 2 of them stacked with 100w from my FT-857D, should be
killer!

==========

Only indications?

At what frequency?

At a distance of two wavelengths you are in the far field. Any improvement in distant signal strength has little to do with antenna/transmitter radiating efficiency which depends only on what takes place in the near field. More to do with less-lossy ground reflections part way along the propagation path.

Very long radials behave similarly to large ground mats laid half way along a two-hop path.

1498. Being confused with two designs of Collinear Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-07 11:26:29 UTC
From: tahamtan@sonra.net
Message-ID: <afdf3dea.0408070326.7539173d@posting.google.com>
Source record: 91319

Hi,

I have read about collinear antennas within the two web sites below:

http://www.guerrilla.net/reference/antennas/2ghz_collinear_omni/

http://wireless.gumph.org/articles/homemadeomni.html

I have made the first one. But before testing it, I have noticed that there is a very essential difference between them. In the first design there is a short circuit between the central conductor and the shielding in all segments as the final 1/4 wavelength segments is a short circuit itself. But in the second design, there is a strict advice that check the complete antenna before using it in order to prevent any short cross connection between the central connector and shielding.

Can anyone describe me what design wil actually work? and if both will work what is the reason of that difference?

Very sincerely,
Farzad

David -

I am not aware of an 80 meter add-on kit for the Cushcraft R7 antenna.
http://www.cushcraft.com/support/pdf/r7.pdf

The Cushcraft R7000 antenna did have an 80 meter add-on option, making the
antenna a R7000 Plus.
http://www.cushcraft.com/support/pdf/r7000-man.pdf

Vertical antennas have very narrow bandwidths (typically less than 70 kHz
for SWR 2:1) for usage on 75/80 meters --
frequency agility is just not typical.

Whether the 80 meter add-on kit for the R7000 or another vertical antenna
could be adopted, is a matter of experimentation.

1500. Multiband HF Antenna Nipping | Bottom Up or Top Down?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-07 14:45:16 UTC
From: kelly@dvol.com
Message-ID: <d22b54c3.0408070645.deec383@posting.google.com>
Source record: 91221

I'm mulling the construction of a "nested HF squalos" antenna. At least three bands, wires for 20, 15 and 10M in a coplanar arrangement on four fiberglass spreaders. Basically a multiband cubical quad driven element with a common feedpoint, single feedline and flopped over into the horizontal position. After wading thru all the modeling comes the real world. I'll cut the wires a bit longer than modeling indicates and start manually tuning the thing to resonance by nipping all the wires a bit at a time using the 259B, etc. Each nip will affect the resonant points of all the wires due to the interactions amongst the wires. The question: Which wire should I start tuning first? I've seen posts which state that one should start nipping from the lowest band to the highest band and I've seen recommendations to start with the highest band and work down to the lowest band.

Which way is it??

Tnx, w3rv

Tho, both will work, the correct one, from my experience with useing DB Products "Green Hornet" series antennas, is the one with the 1/4 wave/shorted piece of coax to the 1/4 wave stinger. Ans as a aside, in vhf service, check for a dead short to the antenna (they flex in the wind, -if you see it go open, or high resistance, when the wind blows, needs replaceing) one thing NOT mentioned, in either of these sites, is the application of Ground Plane radials , however, again, the shorted antenna has a 1/4 wave decoupling sleeve, which should do the same as the radials! All in All, I'd go with the shorted one- and a caution: the pattern of these is VERY NARROW- and close to the HORIZON (omni-directional) - look like drop a doughnut over the antenna! want to mount this as straight up-down (verticle) as possible for max range! As info, Jim NN7K

Hi Farzad,

Work? Perhaps. With the advertised gain? No, not even close.

Both pages have problems beyond your issue of a short/no-short.

The immediate problem is that all sections are NOT half-wave. Both pages handle velocity factor, but one fails to include the velocity factor of the insulating jacket (it makes a difference). However, this is not the only problem.

The formulas used by both pages (with some slight difference in the speed of light) are for an EXTREMELY THIN WIRE antennas. These designs being offered are in fact VERY FAT WIRE antennas. These pages use the commonplace divisor of 2 which is wrong. Given the length to diameter ratios of the materials being used; then the divisor would be closer to 2.5 to 2.7 which is VERY different.

hi i am trying to tune the r7 on 4ft poll, i know they tell you to use 8ft
poll
will this make this much difference,
10 meters is ok
12 meters is ok
15 meters, swr 1.6 at 21.7mhz
17 meters swr 2.1 at 18.111, swr of 1.8 at 18.168
20 meters , 2mhz out 12.455mhz swr of 1.2
30 meters swr 10:1 at 10.150mhz 9.011mhz swr of 5.2
40 meters swr of 2.1 at 6.395
don't know if traps measurements are ok as i got this second hand
measurements between traps are
A 123"
B 10.5/8"
C 6"
D 16"
E 16"
F 25"
I AM IN THE UK SO I WANTED 40 METERS AT 7.05-7.1MHZ
is the 30meter trap not working

Outgoing mail is certified Virus Free.

Does anyone have experience of the antenna of the title, which came with all 3 suppliers info included? I purchased it at Longleat about 5 years ago, but never got round to using it. Now trying to install it at my friend's QTH to get him going

I've just spent a very frustrating afternoon trying to put this thing up, and when it was up, it exhibited a resistance of 200 Ohm between coax inner and outer.

Assumption - error in soldering PL259 - no - still does it. (During which resoldering exercise the bit fell out of the brand-new Draper 100w iron and burnt a hole in the carpet, forcing a hasty exit because of toxic fumes, followed by a hasty re-entry to pick it up because the fumes were increasing and not abating!.)

Then there were incompatibilities between different PL259's, for example, some have a shoulder deep inside which prevents the braid from reaching the soldering holes.

Then a PL259 where the thread of the locking tube was longer than the thread of the SO239 inside the antenna so it didn't lock the outer and the whole plug swivelled loosely.

Separate cable from antenna and both show open circuit, as you'd expect. Couple them together and 200 Ohm loop resistance. Ignoring any RF theory, coupling together two open circuits, one on a PL259 and the other on a SO239 just cannot result in a resistance of 200 Ohms! It's plain ornery DC electricity!

I'm banging my head against the wall! Any suggestions?

What a tale of total ineptitude.

So much for our resident 'real ham'.

They teach youngsters to fit a PL259 properly on Intermediate courses.

What happened to your years of study and experience?

I suggest you contact a qualified instructor and ask for some instruction.

David the R7 instruction manual is on line at URL:
http://www.cushcraft.com/support/pdf/r7.pdf

I had poor results with 40M until I got the mounting mast up to 8 feet and a slight improvement at 10 feet.

A common fault is having the assembly dimensions incorrect -- check every element and components vs the Cushcraft instructions.

Good luck

Richard

I'm not so negative about this colinear antenna as you are. This is a
wireless (WiFi) antenna. I think either would work. I like the basic idea
expressed in the posted articles.
The plans that include the 1/4 wave brass sleeve at the end seems to make
the most sense to me. If Farzad wants an omniazimuth antenna for WiFi, this
seems like an excellant idea. It sure wouldnt cost much to try it. The
'specs' for this antenna must be very broad. The antenna just needs to
work. I would think that it could have 8 db "gain" over isotropic. It
might be unimportant that there is 'beam squint' if it is used inside a
building to extend wireless range.

If Farzad was close to the Los Angeles area, I'd ask him if I could help him build one for zero $$, since I have all the parts needed. I think it would be fun.

Richard, where do you get the information? It would be wonderful to have a map of soil types that goes into some detail. I've downloade the map from the FCC, but that doesn't have any real detail in it.

My interest especially is that my own county has tremendously varying soils and geology (Centre County in Pennsylvania) It would be very interesting to lay a geological map ofer a soil conductivity map and compare.

After a bit of destructive investigation, the problem was caused
by a screwed brass stud - not dissimilar to the 3/8 stud at the
base of CB antennae, but slightly smaller in diameter.

When the base part of the radiating element had been screwed in
place onto this stud, instead of the base screwing onto the
stud, the stud had, in part, unscrewed itself down into the
plastic insulator, by several turns. Unfortunately (for me and my
friend) also in the base was a 4-turn loading coil which had not
taken kindly to being unscrewed by at least 4 turns, and had
deformed so that it was intermittently shorting to the ground
plane through the tarnish of the loading coil.

Now, where to get some nylon rod of 40mm diameter to
turn up a replacement for the insulated base, which was destroyed
in the investigative process?

I did some thinking last night. Specifically, *where* do I want to talk to? All over? Not practical - to the west on the roof I have a large metal structure and 18 miles west the rocky mountains start up. No, I don't want to talk west. North? Yea, right - there are like 5 hams north of colorado. No, north is out. South? Maybe but not really.

No, my main target is those states NE, E and SE of me - Illinois, Virginia, Ohio, Kansas, Texas, Florida - in those areas.

So, if my interests are directed then why shouldn't my antenna be?

A-HA! A beam! But what kind of a beam..... Hmmm - something I could build, cheap (in case this didn't work and I have to go back to plan A) and easy.

A Quad! Yes! And only 3 elements - no more - that way I've got a 3db beamwidth of about 66 degrees. That's enough to cover all of my target areas without a rotor! Even Better! What's more, I won't be picking up as much noise from areas I don't want to hear like S, W & N.

So, off to Home Depot to buy stuff.
Pine 1x2x8 for a boom $1.09
12 - 1/4"x48" hardwood dowels for spreaders @ .37 ea.
Speaker wire for the elements, 3.5 cents a foot.

Total with tax $9.09

4 hours later, it's up & tuned. I was a bit suprised - I worked out a length of 239.523" for the driven element but that ended up resonating around 47 mhz. I eventually ended up cutting almost 7" off it to get it to resonate at the design freq, 50.35 mhz.

I'm worried that my other math may be off, too. Here's the specs:

Reflector - 245.482"
Driven el. 239.523" (original size)
Director - 232.373
Reflector/driven element spacing - 43.495"
Driven element/Director spacing - 35.749"
22g speaker wire elements.
Choke at the feedpoint - 2-5/8" form, 9 turns
air wound rg-58 coax.
Total feedline - RG58 58.5'

2:1 SWR bandwidth - 1.6 mhz - 1:1 SWR @ 50.350

Should I trim 7" off the director? What about the reflector?

Note: a repeater, on the backside of the bean, used to
take 68 watts of FM to key up with the Inverted V . Now
with the beam, it only takes 38 watts.

Hi Mike,

From the soil maps I've sent you, I can only guess that your area is a
Silty Loam to Loam in nature. There is not much Clay content, but
across the state your Sand content varies by 20% and your soil is
dominated by Silt.

You (or anyone who cares - an albeit small population here) can make
their own soil determination through a rather simple technique, but
this begs the obvious that such measurements are confounded by RF
ground penetration and extent of field coverage even within the back
yard. In other words, if you are not committed to take half a dozen
samples of soil, from various depths and ranges from the proximity of
the antenna - then why bother worrying about it? There is absolutely
nothing you can do to change anything - even salting the ground with a
ton of exotic mineral makes hardly a thin veneer largely ignored
anyway.

You might find that there are some interesting correlations between
soil types and conductivity though. And such correlations do not
always toe the line in accord with the oft-repeated characteristics
taken for granted here.

Soil is not a simple system that can be reduced to two variables for a
program. ;-)

Hi All,

It just occurred to me that this is the same soil type as K9SQG
enjoys. Where argument arose over the term "identical," then I
suppose there is some latitude here - but not so much such that Mike
is likely to experience a very low conductivity to that of the same
soil in Kansas. 10:1 variation is more than latitude, or perhaps
longitude answers it? Does the software ask for geographic location?

To this point of similarity, the question becomes: would Mike
experience the same noticeable performance variation in greater radial
length that K9SQG finds? It is obviously not exhibited in software as
this report has confounded Reggie.

Has anyone downloaded this work to make their own determination? How
did you choose the variable valuations it asks to be entered?

Ken,
On behalf of the hams in 6 & 7 land I feel compelled to inform you of how insulted we are that you do not wish to talk with us - we aren't bad folks .....really 8-}

As to trimming the director & reflector, my advice is yes - you should maintain the 'geometry' of a quad. The difference isn't likely to show up [very much] in a VSWR measurement but it may well affect the pattern and F/B ratio. Enough difference to make vs not make a contact I can't say - but as long as you're in a motivated mood you might as well make it "as close to right" as possible. Otherwise, the first time you can't complete a QSO with a guy in some truly far away location and the guy down the block could you'll keep wondering "did that 7 inches screw me up?"

I am curious as to your choice of 22 gage wire: I've only made one quad (a quagi actually) and used 12 gage wire - and I don't have icing to contend with whereas you do. Is the 22 gage going to be permanent or was this more experimental and if it works it will be made more robust (larger wire, weatherproofing of wood)? In any case, from what you mention (power needed to hit a repeater) you've already made a significant improvement in your station and I'm sure that will really be noticed when working simplex.

Have fun & 73,
Howard KE6MAK

I set my dimensions on the ground according to the manual, put the 40M dimension at
the CW end (as per manual) and then put it up at 8 ft. I've never had a
problem and everything came out as per the manual.

Didn't mean to offend - I used to live in Vegas and was raised in L.A.
but the mountains! The mountains! Heck - I'm shocked when I hear
WWVH on 15 mhz! Maybe she's coming in long......nah - couldn't be.

22 g insulated speaker wire is suprisingly robust stuff - mind you I
wouldn't
want to put up a 160m beverage with the stuff but for 10m dipoles, 6m
dipoles & quads, it's fine. I went through the whole last winter here
with a 153'6" dipole made up of - yep - 22 ga speaker wire. Now, it
was wrapped around the building but other than snagging on the
corners it was un supported. We had snow, ice, falling branches - no
breakage.

I found a beacon 5 miles away - 20w into a loop. On my Van Gordon all bander, with the 857's 20db attenuator on, the beacon is S0. With the same pad on but on the Quad, S-15+! The location of the beacon is about 25 degress left of where the quad is pointing.

I also tried the beacon on other antennas at the worst, I can just hear it with a 3' wire stuck into my rigs antenna socket (no att pad). With no pad & IPO off & on the Quad - BOOM!

As to the repeater - I'll shorten the reflector 3" later and see if I need more power to kerchunk it - my guess is yes, due to the fact the repeater is behind the antenna and adjusting the reflector should improve the F/B ratio.....

Neat stuff, these antennas!

My bet is that your county seat does in fact have all the data you need. My county has a couple of books of such things which is updated every 20 years for county planning. This includes flood plains, sand deposits,gravel and specific types of earth which does vary in Central Illinois which is about as far as the ice age moved and left us as the highes point between Chicago and New Orleans. Thus makes us more windier than Chicago known as the windy city. Many years ago it was said that 1/3 of the QSLs for the 9 th district were for a few Central Illinois counties. Top soil in this area has a depth of at least 12" and is black coloured when tilled

OK, I went and shortened the reflector - result? The signal from forward (the CW beacon) dropped slightly and the power needed to key the repeater (on the back side) went *down* by about 1.5 db! So, my F/B ratio got worse!

So, I went the other way - not only did I replace the 3" I took out, I made the reflector 1" longer than when I started. Got down stairs and the beacon had gone from S9+15 to S9+20 and the power needed for the repeater had gone back to 3-4 watts higher than it was before.

Interestingly, resonant frequency went up about 100 kc.

So, back I go upstairs...

This time I remove the director completley! Results? No change in forward gain but a 50% decrease in rearward efficiancy......

Now, back up stairs - I'm gonna shorten the director 3"... brb...

OK, I'm back - put the director back on but shortened it 4".

Not good! The power to hit the repeater went from 48 w to 24w and the resonant freq jumped almost 800 kc! Plus, there was no signal improvement from the front.....

Back on the roof I go.....

OK, I'm back - SWR is back to where it should be, F/B ratio seems back to where it was, forward gain is back....whew!

I'm done for the day - time to kick off my shoes, have a tall glass of ice tea and some dinner (maybe - I'm trying, with 92.5 lbs of success in 8m so far, to loose weight....)

Someone who knows what's what - based on what just happened, can I assume my antenna is pretty close to optimum the way it is?

Ken,
First off, not offended by your choice of where the quad is pointed,
was just tyring to be humorous.

Sounds like you're getting in some exercise with this project!
Offhand I'd say you've got it as good as it gets so just set back and
enjoy it as is. Otherwise you'll also start playing with element
spacing too and then you'd end up making trips up and down the stairs
and still end up about where you are now. As to the 22 gage holding
up well, that's good news: I tend to follow the first rule of
structural design ..... if a little bit is good then more is better,
thus the recommendation for a larger wire.

Howard

HA! Too late! Well, I didn't really screw it up, but I did do a little
experiment to see which way I was going on the SWR since I made the
antenna a littel longer than calculated. Sure enough, the SWR got worse
when I added a bit onto the end. But now I'll have to wit until tomorrow
to remove it. But you're so right.

Good idea. Anything that lessens the "sway pull" on the wires would be
a pretty good thing, IMO.

Put two of them at right angles with coincident feedpoints and tie the
long side of one to the short side of the other.

I came up with this idea about 1954. Has anyone turned EZNEC loose on it
to see what the patterns would look like on various bands?

Hi Art, All,

You have the advantage over Mike and K9SQG in the conductance
characteristic being double or better over them. You also live in a
different (I hope there are those who notice I am not talking about
identicals now) soil - it being somewhere between a Silty Clay and a
Silty Clay Loam. This is to say it has more clay and less sand
content than their soils. This also portends a correlative ... until
you look at more examples to see that theory dashed (soil is not a
simple system reducible to software employing two variables).

To this point of difference, the question becomes: would Art
experience the same noticeable performance variation in greater radial
length that K9SQG finds? It is obviously not exhibited in software as
this report has confounded Reggie.

You (or anyone who cares - an albeit small population here) can make
their own soil determination through a rather simple technique, but I
note the bated response to this subtle offer and find it possibly
correlates with suspended interest (the long way of saying boredom
with the topic ;-) Would it be indelicate to mention it could be done
in the kitchen?

I'll tell ya what - not only have I dropped from 302+ to 209, but I've gone from 1,000 mg Glucophage and 570 units of insulin ($58/1000u) shots per day to no diabetes meds whatsoever. At the same time, my blood sugars have stabilized to the point of being equal to non diabetic numbers, my blood pressure is under control, my cholesterol is improving fast & even my diabetic liver damage has healed itself 60%. All since new years.

All I've done is restrict carbs, calories & processed foods plus daily excercise
on my Bianchi road race bike (10 miles minimum per day).

Eat right & excercise - duuuuuuhhhh.....

Sounds like you fettled a perfectly good antenna. I am surprised you have
not claimed "shoddy goods" and cast it into the bin.

You seem very cack handed for someone who claims to do model engineering and
home brew your own radio equipment.

Just at it did at Westinghouse, the truth is emerging. You can't write
software and you can't do hardware.

Back to shelf stacking in a supermarket.

1539. SWR meter kaput?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-08 12:56:21 UTC
From: Thomas <nospam@nospam.com>
Message-ID: <10hc8njhtreuh89@corp.supernews.com>
Source record: 91260

Recently started to renew my interest in ham radio and so pulled out some old equipment.

I set up a temporary antenna yesterday and connected it to my rig, including an MFJ Versa Tuner II (Model MFJ-949D), purchased about 15 years ago.

Setting the transmitter (Icom-725) to low output power (about 10W) I closed the CW key and the tuner indicated about 15W of forward power, and no reflected power. That is, it "indicated" a SWR of 1:1. Unlikely, to say the least.

The reflected power meter just doesn't move at all. Regardless of band. Thus, I am convinced that something is wrong with it (it has been moved twice since purchase). I did open the case and nothing looks out of order. Touching the reflected meter terminals with an ohm meter causes the reflected meter needle to jump, so it appears that the meter itself is working.

The antenna seems to work very well for receiving. And I am able to "get out", as it were. I can hear myself on a little SW radio I have at 14.2 MHz in AM.

Questions:

Any thoughts as to where to look for the "problem" with the tuner?

Is there another way to determined SWR with just the meters on the transmitter (RF power out) and the forward power meter on the tuner?

Thanks in advance.

73s,

Thomas

You can look at the power and then interchange the input and output of the meter to see what the swr actually is when you are not using the switches in the tuner position but in the bypass position.
Thank I would look at the diode first to see if it good. Being a MFJ you may need to see if any of the connections are loose. I have one similar to that tuner and the first thing I did was open it up and tighten up all the loose screws. Bought It new at a hamfest from a dealer and when I got it home I noticed it making a noise when moving it around. Found a loose nut and washer inside it.

If you were getting Forward power on the meter, then the meter
movement is obviously good.

If the meter was working when stored, that
might likely rule out the most
likely failure--a bad diode in the coupler. It could be
a bad diode, but less likely. My first suspicion
would be a dirty switch contact on the Forward/Reverse switch
at this point.

Now, there is no way you are going to determine lowest
SWR with the meter the way it is. You could install the
meter "backwards", antenna to equipment side of meter,
vica versa, and that would let the meter show minimum
SWR if you had to.

Put a resistor on one of the unused coax connectors on the 949D, 100 or 25 ohms should give you a 2:1 swr.
I put a 25 ohm on my 949D and for 10 watts in read 1 watt reflected. It could also just need recalibrated, I
borrowed a friend's Bird and calibrated both the HI and LOW settings. Works better now.

If I understand your description, the result is two balanced
dipoles arranged in horizontal V's. The low impedance of the
two long wires at their 1/2WL resonant frequency will keep
much current from flowing in the shorter wires. It seems
your idea is just two paralleled dipoles with 90 degrees
between the dipole elements.

Using low power, hook up the antenna tuner backwards so the
reflected power reading is actually indicating forward power
and vice versa. If the reflected power meter needle doesn't
move, you've got a hardware problem.

Been looking for the same, myself. Best I've found is
http://www.davisrf.com/amateur.htm
$36.50 for 1000 feet bare 16-guage.

Otherwise, places like Home Depot have 500 feet bare 8 guage for $69.

Guess it depends on how heavy you want to go.

I did four uninterrupted years on one gig for DuPont in the 1980s. Not
counting some very long weekends in FL and such. Some of which I
hustled them into financing.

> The going rate is just not in the $100/hr range in the midwest. That's pushing

For the most part agreed. Depends on the game though. $200/hr. is SOP
for "technical experts" who attach themselves to lawyers chasing big
insurance payouts in liability suits. Did that one too. Wild trip
every engineer needs to try at least once for the sake of acquiring
some "perspective".

And when you get time after tightening the screws, drill out those rivets on the coax connectors and replace them with real bolts and nuts. If they aren't loose yet they will become so, or at least they have on my MFJ tuners. You get pretty much what you pay for with these cheap boxes, but after a little tightening and redoing a solder connection here and there, they become pretty serviceable.

Hi Brian,

Try both ways and work toward the middle.

Nah.

Common advice I've seen is work with the most wire first.

> Common advice I've seen is work with the most wire first.

Common advice using common sense. An 80m dipole can be close
to resonance on 10m (big effect) but a 10m dipole is completely
non-resonant on 80m (virtually no effect). And a 5% adjustment
to an 80m length equates to a 40% adjustment to a 10m length.
In mathematical terms, tuning the shortest wavelength antenna
first is a *diverging* infinite series, good for sun tans
but bad for ham operating time.

Lowe's also offers solid #16 wire in four colors and a sharp knife
removes the insulation from a 33' radial in less than a minute. But
what is your objection to insulation for radials? (Ground around here
in East Texas is invariably more inductive than conductive at HF-RF.)

Well, that was a question I posed awhile back -- I'm trying to enhance
a puny ground rod with buried wire (this is a station ground, not an
antenna ground), and figured bare wire would be more "one with the
earth" for such purposes. Would the insulation, or lack of it, make a
difference?

>a wire antenna?

Only for mechanical strength on the ground surface. The current in the antenna equals the total current in all the radials combined, so (I-squared*R) losses in individual radials are very low. For DXpeditions and field day stations where the radial mat only has to last a few days, large amounts of very thin wire give the best results per pound of copper.

I happened to find a large reel of something close to US#16 (18swg) enameled solid copper at a very good price, and that has worked out pretty well - it's easy enough to handle, but pretty hard to break by accident.

For radials, insulation doesn't matter either way from the RF point of view.

However, I wouldn't ever choose bare stranded copper for burial in almost any kind of soil. The RF resistance of corroded stranded wire increases a lot more rapidly than the resistance of solid wire with an equal film of corrosion. (The skin effect forces the RF current to stay on the surface in both cases, but in stranded wire the current also has to hop between strands... or try to.)

Insulated stranded wire, to keep the water out? Well maybe, depending on the kind of ground, the toughness of the insulation, and the kind of price.

Sorry Bob, my career was in digital electronics, where if it wasn't
a one or zero, it was broken. For the answer to your question, you
need to consult an analog RF engineer where the exact crossover point
between conductivity and dielectric constant is discussed.

I am personally located in a low conductivity area in East Texas so
I am assuming that the dielectric constant predominates here. If you
are in a very high conductivity area, e.g. Padre Island, TX, all
you need is an electrode in contact with the Gulf of Mexico with no
radials required. If you are in a very low conductivity area, e.g.
Northern New Hampshire, your radials need to be trimmed to a resonant
length whether insulated or not.

Fpr RF or AC leakage??? It should be bonded to the service entrance
ground rod to start with.

Let's look at it your way and try some numbers. Suppose the original off-center fed wires are each 132 ft long, split 44 ft from one end. (I realize that some recipes use factors slightly different from 1/3.) Your two V-shaped dipoles are 88 ft and 176 ft long, each split in the center. The longer one will have half wave resonance at approximately 2.66 MHz. The shorter one will have half wave resonance at twice that frequency. Higher-order low-Z resonances will occur at frequencies roughly certain integer multiples N of 2.66 MHz. Odd values of N provide resonance for the 176 ft dipole. Values of N which are twice an odd number provide resonance for the 88 ft dipole. These higher-order resonances will not be too near 80/40/20/15 except perhaps for N = 5 (13.3 MHz) near 20 meters. The resonance frequencies calculated this way will be too low since I am using the 468 figure which incorrectly allows for end-effects at voltage maxima inside the wire as well as at the ends. That's why the 13.3 MHz figure worries me a bit. The WARC bands are another matter.

But I don't think looking at it as two dipoles in parallel is the right way to analyze the problem in the first place.

In the Boston area CONSULTANT engineers got paid $1000/day plus expenses
in the early 80s. And they were hired by the day! And they consulted,
which means they did NO engineering work but critiqued, reviewed and
suggested approaches, methods, etc.

Contract engineers, at the 20+ year experience level in a specialty,
were billing at between $80 and $100 per hour. If this is a contract job
the rate is typical.

When I retired from engineering in 2000 my company was billing between
$140/hour and $160/hour for my time.

Ok here is a question that I should know the answer to but I don't as I have never used a ground mounted vertical.

Please can someone tell me if it is ok to use plastic insulated wire for ground radials?

Thanks

Jon G2FHF

Go to a farm supply store and look at their aluminum electric fence wire.

They will also have steel electric fence wire which will be cheaper, but it
will not last as lone.

Heh. Been there, learned the hard way when to leave well enough alone.
If you intend to keep on with antenna experiments you ought to
consider buying one of the antenna anylyzers. They really make quick
work of the sorts of things you're doing Mike. There are some bucks
involved but I've saved *hours* of drudgery with my MFJ 259B analyzer.
No need to put any TX power into the antenna just to tickle the SWR
bridge, it does it's own tickling. With batteries in the analyzer you
can do it all in the yard and not have to run back & forth to the
shack.

I think I will. I just noted a big difference between my Outboard S-Meter and my rig's. The lower levels correlate just fine, but at higher SWR's they diverge in a big way.

Choose copper radial wire for its mechanical strength in the ground. 18 to 14 gauge is OK in fine, not rocky soil. Bus-bars and plates are a waste of copper.

Thin insulation makes no practical electrical difference at HF. In theory, the thickness of insulation actually reduces resistance-to-ground loss because the insulation replaces the lossy soil with a lossless capacitance. The effective diameter of the copper is increased by the insulation thickness.

If you take matters to the exteme and have elevated radials the ground loss is obviously minimised. You can get away with only 3 or 4 elevated radials.

Enamelled magnet wire will be easier to obtain and possibly cheaper than the bare stuff. Get it cheap in relatively short lengths from electric-motor and transformer re-wind plants. They often have scrap lengths on reels and may be glad to get rid of it.

Enamelled wire is also a protection against corrosion and so improves durability.

A single ground rod is equivalent to a single radial of slightly greater than the same length and is practically useless.

Reg, G4FGQ.

hi dave,

good advice but sometimes not possible !

The ccr topic was covered at length on http://www.eham.net
in antenna restrictions forum.

Just about all new construction here in the RDU NC area is CCR !

The banks won't lend the money to the developers unless they have ccr.

On the other hand, if you travel out of the area and into the country you
may find property to build on but at the cost of a long commute.

Another ham did research on land value with and without ccr, and guess
what ? The real estate without CCR appreciated more then the land with ccr.

Hello,

I am looking for some advice on if the ground system featured below is
sufficent or should be upgraded. It consists of:

- 3 ground rods 10' each around the tower (bonded together)
- 2 ground plates (one outside, one in the shack, also bonded
together)
- lightning arrestors and/or feedthrough adapters
- tower to mast ground
- interior coax switch (not shown)

I provided some pictures below:

http://www.telusplanet.net/~homac/exteriorground01.JPG

http://www.telusplanet.net/~homac/exteriorground02.JPG

http://www.telusplanet.net/~homac/exteriorground02a.JPG

Hi Lloyd. Certainly an extremely professional appearance to the work. Great to see such attention to detail as your station provides. Feedback now.....

Is that nice drainage-rock surrounding the tower base only a couple inches deep? Seems the ground rods lose effectiveness for whatever depth that rock is. Would have been fine to sink them a full 10' even after digging a 1' deep trench and covering with topsoil. Besides gaining addtional effectiveness from the ground, it's the exposure to air that will cause the most need for future ground system maintenance.

Ground rods around the tower are very close together, is there room to add additional ground rods from at least two of the legs at a distance of 10-20' from the tower?

Tower is very close to, but not bonded to the house. Are there metal rain gutters or metal flashing close by? Bonding to them is indicated, if so.

Is that a picture of coax shield grounding design, using the SS hose clamps? Stainless steel is a very poor conductor and works when nothing else will - but a copper or bronze shield-ground would be better. Andrews Wire and I.C.E both make nice ones.

Interior surge protection for wiring is going to be a serious issue, when a tower is that close to the structure. EMI from a direct attachment so close will be a challenge that might indicate 200% sizing of neutral wiring, double-ended surge protection and some very good bonding. Ground Potential Rise will start right at your station's single point ground with a tower so close - therefore perfect bonding including the connection to the AC service ground is essential. In that respect, those attractive looking insulated wires bonding the station equipment to the single point ground may be inadequate. The bonding is the only protection from such close aboard GPR, and individual heavy, wide copper straps could do a much better job than the

wiring shown.

All in all, I think the only major defect is the lack of additional ground rods, as when a tower is right next to you, the desired direction for attachment current is away, away, away. Carry it away with a ground field that uses very heavy low impedance conductors and at least two more ground rods. More is better considering where your tower is.

Best regards,

Jack Painter
Virginia Beach VA

We have REPLACED lossy soil with lossless insulation.

But now there's no lossy soil in contact with the wire and most of the loss occurs in that layer of soil directly in contact with it. Given the wire diameter and diameter over the insulation the improvement can be calculated.

Make the wire insulation 6 feet thick and see what happens. You have something like very low ground loss elevated radials.

Looks like a pretty good start. I would add a Polyphaser rotator surge protector to those conductors passing through the terminal block on the ground plate.

Make sure everything in your shack is bonded together, including your computer etc. Add protection to phone lines. etc.

The other poster mentioned more ground rods. That is a good idea, arrange them to direct the current away from your shack.

Have you bonded this ground system to the rest of the house? If not, do so by running a conducter to the utility ground rod. Be careful doing so as there may be a slight potential difference that will go away when bonded. Also check your water supply. Is it mettalic? Then bond it as well.

The RF will take the path of least impedance. The currents
will equalize in the long legs. The currents will equalize
in the short legs. One of those currents will invariably
be higher than the other one, i.e. the current will be
higher either in the long legs or the short legs depending
upon frequency.

How about a Turnstile? Even a 6M Turnstile-Reflector should fit inside
your 10 foot envelope, but you may not want/need the overhead propagation.

Anybody know anything about the internal configuration
of these?

I bought one on behalf of my friend yesterday at Wimborne
to replace the 5/8ths one (not a colinear - misunderstanding)
that had been badly manufactured (q.v.)

On this Diamond, it gives an SWR of 1.01:1 and yet a DC test
shows no continuity between the centre of the coax and the
vertical radiator - the outer of the coax shows a dead short
to the monopole.

How are these things wired internally? - Mystified

1592. Re: moxon vs quad

I've compared those two on 2 meters. Both antennas were homebrewed based on W4RNLs' info on his web page.

The moxon has deeper side nulls, but they are at different angles than those of the quad. The front-to-side nulls on the quad are pretty much at 90 degrees, while the moxon's nulls were more close to 120 degrees. I can't quantify it beyond S-meter readings on my VX-5R, but the moxon nulls were deeper by 2 or 3 S units on this particular VX-5R. Your mileage may vary.

Directly to the rear, the two antennas were about the same.

I couldn't determine any gain differences, nor measure a 3db beamwidth, but the beamwidths were similar for horizontal polarization, to about 60 degrees either side of straight ahead. Then the yagi started dropping off. The moxon dropped off more slowly until well past 90 degrees.

Vertical polarization is different, but you probably are not planning on that for 20 meters. Vertically polarized, the moxon had a nice deep null directly to the rear, while the pattern on the quad was more or less unchanged from its pattern horizontally polarized. The moxon's vertical beamwith was also quite broad.

In sort, what I saw playing around with the antenna's was very similar to Cebik's modeling predictions.

All of my tinkering was done listening to local repeaters, with the antennas at about 15 feet height.

For 20 meters, it will probably be a matter of which is easiest to build and support. A monoband loaded yagi might be easier to homebrew for 20 meters.

73,
Keith, W4KAZ

Why, it isn't complicated. There is a matching network, details depends on
the version you have. Some have a tapped parallel tuned circuit, some a coil
tapped with a C to the monopole.

So much for our resident expert.....

I had one of those Diamond ones.Couldn't make it work.
Used the Aluminium for something else.
(if its the 5/8 over 5/8 you are taling about).

It quite possibly is - both halves of the monopole
are just that bit longer than arm's length.

Yes - I've done that before - last year during a lull in
interest I used the aluminium elements of an HF beam
kit to make up the legs for the testing horse for
my clocks, on the basis that the cheapest thing that
you can buy is always more expensive than the most valuable
thing in your junk box!

> What I need is
> a omnidirectional horizontaly polarized economical gain 6 m antenna.
> Anybody got ideas?

In a fairly old (1970's-era) copy of the ARRL VHF book I picked up recently at a swapmeet for a dollar, I found plans for a horizontal omni design called the "big wheel". If I recall correctly, it consists of three full-wavelength horizontal loops, fed from a common central feedpoint, with each loop (bent slightly out of circular form) forming a 120-degree segment of a wheel-shaped structure. They're fed in parallel, with an inductive hairpin strap for matching.

The "big wheel" is said to give significant gain over a bent-half-wavelength-dipole "halo" antenna, and I believe it has gain in excess of that of a turnstile. Two halos can be stacked quite effectively - the book said that the improvement in useful gain is often more than might normally be expected from stacking, apparently because a stacked pair often has a main radiation-angle lobe at a lower angle than a single wheel.

Sure looks economical - you could build one out of stiff copper wire, or aluminum or copper tubing, plus some homemade clamps and the matching strap.

1600. PHASING HARNESS FOR 2 BAY CIRCULAR POLARIZED ANTENNA?????

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-09 20:16:12 UTC
From: radio913@aol.com
Message-ID: <1d15af91.0408091216.911d128@posting.google.com>
Source record: 91121

Good Evening,

I'd like some advice on building the phasing harness
required for the following antenna:

http://members.tripod.com/~AMN92/cp_ant.htm

It certainly would use 75 ohm RG-6, and i
believe it would be 1 full wavelength, fed in the
center, with the two bays on either end (1/2 wave
to each antenna). You would also need 4 turns of
3-4" diameter coils in the RG-6 at the feedpoints,
to serve as baluns, which decouples antenna currents
down the braid.

So in theory, this should be two 100 ohm
impedances in parallel, for a total of 50 ohms,
which can them be fed with garden variety RG-8 or
RG-213.

Any advice or input is greatly appreciated.

Slick

Harmonics of the switching power supply which is on all the time so the remote can function. RF transparent case and a dipole consisting of the AC cable for one leg and the cable and dish for the other. Probably more efficient than anything a ham could come up with for a disguise antenna. I'd be curious what the fundamental is, but some of those pulse width modulated supplies are getting pretty high in frequency.

Source record: 91129

Well, I found hexbeams pretty hard to build for 2 meters.

I did build a hex for 17, 15 and 10 meters. That's a fairly finicky design for homebrew--its tough to get the desired SWR bandwidth to match up with the desired beam pattern characteristics. Small variations in the geometry varies the resonance, even on those HF bands. It was hard for me to make a multiband hex funtion properly.

If you look up my postings on the hexbeam yahoogroup (user id there is kg4eqd), I made some pertinent comments there. Some of my comments are disputed by other builders, so use your own judgement.

I also found it difficult to reproduce the results from one hex to the next. Probably, my own shoddy construction was simply not precise enough, particularly the hex support. Moxons and quads are simple by comparison.

I spent LOTS more time tuning and adjusting the hexes than on any other project. It was fun in its own demented way.

Once tuned, they did have good f/b ratios, even at low heights.

I left the multibander up. It got ripped by an ice storm here a couple of winters back, and I don't intend to rebuild it.

With all that said, my homebrew hexes had a really nice null, were not prone to yagi static noise, and probably had a bit more gain than a dipole. The f/b ratio was much better than a two element yagi at the same height, but I doubt it had the same amount of gain as a two element yagi. Maybe close, but certainly not more.

If you have restricted space, I satisfied myself that the hex antenna works well for a restricted space. I'd recommend plunking down the "small fortune" for the commercial, rather than try to build one.

Unless you just enjoy demented antenna fun....

If you place multiple loops in the correct order
there is no need to use a a harness. The trick is to connect
the loops in the correct order depending on the size of the loops. Feed
impedance is one of personal choice. This design easily beats the design
featured, A antenna program with variables will asign the correct distances
between and the correct order of the partial loops.
Have fun

1610. Taylor W2OZH Loop Antenna for 75-80M

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-10 04:51:46 UTC
From: nospam_deepsea_77@yahoo.com
Message-ID: <411852a1.14972530@news1.news.adelphia.net>
Source record: 91131

Questions on this antenna:

http://www.pcug.org.au/~prellis/amateur/space-miser-80m.html

1. Think this will stand 150 watts AM? That 300 ohm twinlead looks a
little fragile for a capacitor...

2. How critical is the actual ratio of length to height? Seems to
indicate a length of about 23-24 ft (upper end of band), and I only
have about a 20 ft run to work with...making the height a bit
taller... so the whole thing might come out a bit taller and a bit
narrower, once it was hung.

Thanks to the group in advance,

Lin/KJ6EF

Hi Lloyd,

Looks like a nice installation, although your grounding rods might be
placed farther apart, or augmented by some heavy gauge radial wires
(depending on your local ground condictivity).

What I did note missing was the mention of 'lightning chokes' wound in
the coax lines decending from the tower. These are basic to lightning

protection for broadcasting towers, but I've rarely seen them implemented by hams.

The idea of a lightning choke is to add a small amount of inductance to the coax so that if a direct lighting strike happens, the instantaneous current flowing though the outer jacked of the coax into your lightning arresters will at least have some amount of impedance limiting the current magnitude, thus reducing the probability of destruction of both the coax and the the arrester itself.

These chokes are more often than not implemented by winding a dozen or more turns of coax around a form (say a 4" diameter phenolic tube) prior to the arrester or spark gap.

Dr Slick

If you intend to use this antenna to transmit, as indicated in the article referanced, I couldnt be of much use to you. If you only want a omni-azimuth circularly polarized pattern in the VHF band, I could probably help.

Harry, that winding of coax may be useful as an RF choke, but it is most certainly not a lightning choke, and will act more like an air-wound transformer than anything else. Not only is this not specified for any lightning protection systems, it is specifically warned against in many.

> Hello All. First let me comment that the lightning mitigation techniques
used are better than many ham installations. That being said, I would
increase the conductor size between the tower legs and the ground rods.
When I saw these, I thought a "fast acting fuse." The amount of current
that the tower can handle cannot be safely terminated to ground with smaller
conductors.

Also, the screw terminals need to be checked periodically because they will
loosen themselve due to "cold flow." Why not repace them with crimp types
and then solder the crimp with a torch as a back up? I am asuming that this
device is covered by something to protect it from rain, etc?

Actually it appears as if some manufacturers only measure the
directivity and express it in dB :-), completely ignoring the
efficiency, which is often quite low in "exotic" antenna designs.

An exotic antenna design with directivity 10 (10 dB) and 10 %
efficiency will have a 0 dB gain and will produce the same effective
radiation power (ERP) as an omnidirectional (directivity 1 or 0 dB)
antenna with 100 % efficiency when using the same transmitter power.

>differentiation.

In the _far_ field both the E and H fields are inversely proportional
to distance and have the 120 pi (377 ohm) relation (impedance) between
the fields. However, in the _near_field_ (<< 1 lambda) the 377 ohm
relationship is no longer valid and the magnetic field is inversely
proportional to the square of the distance, while the electric field
is inversely proportional to the cube of distance.

Summarising the graph from an article by Lloyd Butler VK5BR in Amateur
Radio, August 1990: The output voltages from both E and H field
antenna system are calibrated to the same value at 1 lambda (i.e. in
the far field). The antennas are moved closer, when the E and H
antennas are moved to 0.05 lambda, the E antenna delivers 50 dB and
the H antenna 40 dB (relative to 1 lambda) i.e. the H-field is 10 dB
quieter. At 0.005 lambda, the E field antenna output is 110 dB and the
H-field 80 dB, i.e. the H field antenna is 30 dB is quieter.

Thus, with same far field sensitivity, the sensitivity to very local
interference is attenuated considerably when _only_ the H field is
used. However, at 3.5 MHz and 80 m wavelength, 0.05 lambda corresponds
to 4 m and 0.005 lambda to 40 cm, so we are talking about really close
noise sources. At even higher frequencies the number of potential
interference sources is dropping within the 0.05 (or even 0.1) lambda
radius from the receiving antenna, in which the H antenna has an
advantage.

However, on the 135 kHz LF band (lambda 2.2 km), the distances would
be 110 m resp. 11 m, thus much more unwanted interface sources could
be eliminated.

Shielding the H-loop simply prevents the stronger E field from
entering the loop and thus destroying part of the advantage of using
the H-antenna.

Well, so far the best advice was from someone who will
remain anonymous, who emailed me personally:

> If you're hooking up two of these antennas in parallel, and using a
phasing harness which is one [electrical] wavelength long with a
feedpoint in the center, then it doesn't matter whether you use 75-ohm
coax or a different variety. The 1/2 wavelength of coax from the
antenna connection point to the central feedpoint will "mirror" the
antenna's impedance down to the central connection point - the coax's
impedance drops out of the equation.

You might get slightly lower losses (all else being equal) if you use
a 1-wavelength piece of 93-ohm coax. As this is close to the 100-ohm
antenna impedance, the SWR on the coax will be quite low and you'll
have low resistive losses in the cable. This is probably not a
significant issue, though, when you have only 1/2 wavelength of
attenuation to worry about.

> You would also need 4 turns of
>3-4" diameter coils in the RG-6 at the feedpoints,
>to serve as baluns, which decouples antenna currents
>down the braid.
>
> So in theory, this should be two 100 ohm
>impedances in parallel, for a total of 50 ohms,
>which can them be fed with garden variety RG-8 or
>RG-213.

Yah - that'll work.

The parallel tubes to the feedpoint form a version of the "universal
stub" impedance matching system. A fully-generalized universal stub
is usually made 1/2 wavelength long (from the antenna elements back to
the mechanical mounting point). You then tune the feedpoint impedance
(resistive and reactive) by adjusting _two_ things - the point at
which the feedline connects to the stub pipes (as done in the
instructions on this page), and also the position of a shorting strap
which is connected directly between the stub pipes at some point
between the feedline connection and the mechanical mount point. A
universal stub provides you with a very great amount of flexibility in
choosing your feedpoint impedance.

Another method sometimes used to feed antennas like this, is to use a
halfwave coaxial balun rather than a choke-balun loop. You'd
construct the usual sort of 4:1 half-wave coax balun, connect the

high-impedance balanced side of this to the stub/support pipes, and drive the low-impedance unbalanced side from your coax matching harness. This seems to be the method favored in the ARRL's VHF book (older version, at least) for feeding balanced antennas from a coax... I believe it provides better, more-predictable current balance than you can get using a choke balun, as long as you can accept the relatively narrow bandwidth of such an arrangement.

To use this approach with the antenna in this page, you'd certainly need to move the position of the feedpoint pipe clamps, since you'd want/need to connect at a higher-impedance point on the stub arms. You might find it necessary to cut the stub arms somewhat longer, and use a separate shorting strap - i.e. convert to something closer to a true "universal stub" arrangement. Might or might not be worth the trouble.

I'd just start over on the plugs.

Get some standard PL-259 plugs. Not junk, but good ones (try The
Wireman if you don't have a local source).

Get a 120 watt or better soldering iron -- the Weller SP-120 or 175
are good ones. You need plenty of heat to properly solder the braid

through the little holes in the barrel.

Open your ARRL Amateur Radio Handbook to chapter 22. Precisely follow the instructions and measurements for fitting the coax to the plug.

Replicate the instructions and you cannot go wrong.

Otherwise, order some coax with the plugs already on it :-)

Use two concentric PVC pipes, the diameter of the smaller one large
enough to admit the twin lead and the diameter of the larger one large
enough to keep the surrounding ground far enough away. I should think
that 10 times the twin lead wire spacing ought to be far enough.

Centering the twin lead inside the inner PVC pipe is unimportant,
assuming that the PVC is low-loss stuff. Centering the inner pipe inside
the outer pipe is important. Keeping water, ground, and other things out
of the space between the pipes is important.

Make sure you don't have common mode current on the twin lead; it won't
radiate very far if you do, but you may overheat some earthworms.

Or you could just use coax and avoid the problem ;-)

> Jack Painter
> Virginia Beach VA

Jack, while I'm sure that you believe this, I really can't guess where
you obtained such IMHO such massive misinformation.

First of all, it is the purpose the the coiled coax to act as an
inductor (r.f. choke) because this is how it resists the very rapid
di/dt common mode characteristic associated with a lightning hit, thus
limiting the peak discharge energy that the following spark-gaps and
lightning suppessors must absorb and reducing the overall peak impulse
power damage potential.

It's basically a brute-force version of the common computer technique
of placing a ferrite torroid around cables to attenuate their common

mode impulse transmission/conduction ability. Realize that with sufficiently low SWR, currents through both the inner conductor and outer shield of a coax are equal, summing to zero, hence there is no net electromagnetic field produced. The same is not true for a common mode impulse traversing the transmission line. The bottom line is that only the common mode impulse resulting from a lightning strike will experience the results of the "choke".

I'm not sure why you would believe that a coil of coax would act like a 'transformer' of any type, unless the SWR is truly enormous, a probem in itself. A case in point is that in both proton synchrotrons (typically operating in a swept frequency range of roughly 3-30 Mhz), and in large phased array radars (some of which operate in the UHF range) employ multiple feeder coax transmission lines that are cut the the same electrical length, with the cable lengths in excess of the required physical run length being coiled up somewhere in the system. There is no net significant electrical effect on the cable's transmission characterists in either case.

Prior to completing my degree work at Drexel, I spent 8-years installing and maintaining broadcast transmission systems ranging from 5-Kw to 50-Kw. This included 5 years as chief engineer in one station (WBUD in Trenton, NJ) plus part-time work for WFIL, WCAU, and KYW in Philly. (Additional work in 4 or 5 smaller stations.)

Quite honestly, I can't remember a single one of these that did not protect their very costly antenna installations, transmitters, and on-air reliability without lightning chokes employed in their transmission lines. Still, these broadcasters use equipment that, in general, nothing more sophisticated than your average ham station, but on steroids! True, the average AM broadcasting tower usually exceeds 200-feet, but in an intense lightning storm, a 40-foot ham tower is fully capable of experiencing the same energy lightning hit!

I purchased my first ham receiver, an SX-71 from a ham named Bob Rutkowski (sp?) in Trenton, NJ. A day or so before I picked it up from him he took an evidently direct lightning hit on his 40-some foot crank up tower holding a 2M beam that was attached to his house. He had grounded the outer shield of the RG-8U coax at the based of the tower, but without a lightning choke in the coax, the hit simply vaporized the majority of his RG-8U, his grounding connection, and most of the final tank circuit in his rig in the basement! Not a pretty sight!

Realize that a commercial radio broadcaster has to survive episodes like this without disruption of their operations. Hams don't. Still the emulation of the broadcaster's time proven protection techniques involves only a small additional cost to an otherwise excellent installation.

For more information, see:

Edmund LaPort, "Radio Antenna Engineering", McGraw-Hill Book Company, New York. (My issue carries a 1952 copyright, still it's an 'oldie but a goodie' with many subsequent editions -- and AFAIK is still the bible of the broadcasting industry.)

IIRC, early editions of the ARRL Handbook also described this protection technique (likely pre-1970) in the days when most hams built their own rigs.

Harry C.

p.s., Jack, I'd love to hear a citation where "it is specifically warned against", and why.

What makes you think I am talking about a modeling program? I have been playing with antennas for 45 years. I can work my way through EZNEC, and I had to learn that also.
Maybe you should spend some quality time with a good modeling program. I think you will find the results agree with that vast amount of practical experience you have.

Twist the twin lead two or three turns per foot just so it doesn't kink or
try to unwind, and pipe in a pipe would be a plus.

Yes, that does seem a reasonable aproach if you want to use the antenna that you describe.
It does give me thought about the new revolutionary antenna and the impact it will have on radio.
Since antenna gain is going up I assume that tyhe FCC will force amateur operators to rein in their power to say 400 watts max.
It also suggests that many cell towers will now be redundant and cell phones will have a laminated circuit board
antenna that will fullfill the dreams for which the fractal antennas.had hopede for.It undoubtedly is the same antenna that I alluded to earlier as they point to wide band as well as antenna size and gain as well as distributed loads around a monopole which in itself
provides higher impedances than the norm of a 5/8 whip. With the higher gain antennas I can't see anyway that we can hold on to the
10 metre band as truckers will now require more bands as interference increases.
The good thing that will come from this new antenna/patent is that it will show that hams can provide technology even tho the new antenna
does not have the appearance that is earth shaking and all will say when they see it that they 'knew the design all the time' and just
didn't get around to making one(personal experience showing here). Mark my words, the naysayers and know all's on this group will change there posture overnight
and people will then accept the advantage of loops and their close coupling advantages which is distinctly different to mutual coupling
that is oft bandied around..This fits nicely with the combination loop/dipole antenna once I resolve how to calculate the actual inductance of the arrangementi
Amateur radio is now poised to enter a new phase in the hobby as will wireless computors.
Slick I suggest you hold off building that antenna and harness.and wait and see if this new antenna better fits your needs.
Cheers and beers

On reading your comments, Art, my feeling is that you've swallowed the
glowing claims in the original press releases hook, line, and sinker,
and as a result you are greatly over-estimating the likely impact of
this "revolutionary" technology.

I'll make some counterpredictions.

>Since antenna gain is going up I assume that tyhe FCC will force amateur
>operators to rein in their power to say 400 watts max.

I predict that this "new" technology (which from what I read is not
actually all that innovative) will have little practical effect on the
gain structures of most amateur-radio antennas, at least as far as HF
antennas go. Although it might be possible to use it to reduce the
size of some antennas (for a given amount of gain), I doubt that it
will be applied in ways which result in significant increases in
directional gain for amateur antennas. High gain isn't always a good
thing.

Counterprediction: it will _not_ result in FCC rule changes to reduce
maximum-legal power.

>It also suggests that many cell towers will now be redundant and cell phones
>will have a laminated circuit board
>antenna that will fullfill the dreams for which the fractal antennas.had
>hopede for.

It might reduce the sizes of the antennas used in cell phones.
They're pretty tiny already.

It almost certainly will not be used to increase the gain of those
antennas. High directional gain in a cellphone is as likely to hurt
performance as help it.

It might reduce the sizes of the individual antennas on cellphone
towers. I really doubt that it will reduce the _number_ of such
towers. Cellphone tower placements are often dictated by the number

of channels available vs. the number of calls to be handled, and the antennas are deliberately designed with controlled look-down gain patterns so that towers can be placed closer together without interfering.

High gain is, again, not necessarily a good thing. Aiming the gain pattern "further out" to increase coverage far away from the tower, and reduce the need for additional towers, would require boosting both transmitter power and receiver sensitivity to fill in the near-in pattern. It would probably also require increasing the number of channels per tower. Not necessarily a good idea, economically.

Counter-prediction: this development will not, in and of itself, result in a reduction in the number of cellphone towers.

> It undoubtedly is the same antenna that I alluded to earlier
>as they point to wide band as well as antenna size and gain as well as
>distributed loads around a monopole which in itself

>antennas I can't see anyway that we can hold on to the
>10 metre band as truckers will now require more bands as interference
>increases.

I view this as a minor effect on the 10-meter/11-meter question. Issues such as FCC enforcement (or lack thereof) will have far more of an effect on the viability of the 10-meter band.

Counter-prediction: lots of commercial CB companies will jump on this bandwagon and start marketing versions of this "new, revolutionary" antenna structure; many of the claims made by such manufacturers will be deceptive or fraudulent, and the actual effect of the fielding of such antennas into the CB user community will be negligible-to-minor.

>The good thing that will come from this new antenna/patent is that it will
>show that hams can provide technology even tho the new antenna

>that is oft bandied around.

It seems to me that you are leaping to the conclusion that this "invention" ties into your own work and ideas. I see little so far to justify that.

> This fits nicely with the combination
>loop/dipole antenna once I resolve how to calculate the actual inductance of
>the arrangementi

When you do, please provide some accurate and reliable details, so
that others can reproduce your developments and study them. Such have
been lamentably absent, I believe, in your previous discussions.

David
Idid describe an antenna that will do all the things that the new patent claims and
it would not surprise me i9n the least if it turns out to be of the same design.
I am not a guru so I am not a prisoner to past accomplishments and am able to focus
purely on max radiation per unit length. Tome the loop is a prime example in that it produces
not only more gain per unit length but also has an additive vector radiation in a similar way
centrifugal forces add a vector even tho the electrons
have a constant speed. It does not take a rocket scientist to visualise that an antenna
with a figure 8 circuit would change the radiation field.(clockwise + counterclockwise radiation)
The other point to remember is that true coupling can increase the current in an element
while reducing its voltage and it is current which we hamms are interested in.
Ofcourse if your radiator melts then it shows good coupling and the element has to be larger in diameter.
Now I know that what I say is basic but it apears that hams are locked into a rut when thinking about
new design and if the new patented antenna melted then I suspect he under estimated the increased
current created by coupling. Now because feed impedance is so important to the ham it will be important
to have a unconnected vertical placed inside the coil perimeters which allows by coupling the ability
to meet impedance requirementst
Now David I know hams do not like to pursue the idea of maxcimum radiation per unit length but
if you have a computor program that can use variable dimensions to meet specs then I have provided
enough info for those that are interested but I suspect that most are inately lazy and prefer to0 await the unveiling
at the end of this month. By the way in the description of the multi loop I made no reference to use of
clockwise and counter clockwise travel a statistic that is very important as is the center pole.
Am I sold on the idea of a different aproach to antennas, you bet I am as this aproach provides a

flattening of the take off angle on the horizon at the expense of higher
angle radiation which for cell type frequency
is wasted energy
Cheers and beers

They used to make shielded 300 Ohm line. You could run that through
anything, so long as it is dry.

Thank-you for the advice to this point. I think I will invest in the
rotator cable ground. Not sure what to do about the lightning choke.

I don't mind replacing the antenna/mast if I receive a direct
lightning hit, I just dont want to turn be fried to a crisp.....

Hi Art,

And don't forget, it was 16 or 17 dB less efficient than the common
antenna.

Dqavid just to clear some things up with reference to "gain"
There is no energy created or destroyed here, all I am doing with this
design is "flattening"
the 3D pattern that you see when you have a vertical whip style antenna.
Thus the radiation can be "pushed"
to augment the usefull existing gain on the horizon whether it
remains purely omni-directional or slightly directional..
I suppose that this can be seen as the various loops in the column have a
redirectiive effect on
high angle radiation emanating from the lower coils,
I'm off to bed
Cheers and beers

Hi Harry - well, the web is FULL of massive information, and the old trick
of coiling coax for lightning protection is simply not specified any longer.
I will look up the sites which warned against it, citing amplification of
EMI by such a manuever, and get back to you.

> power damage potential.

Arrestors AND shield grounding are specified at the TOP and BOTTOM of the towers, and AGAIN at the facility entrance. No coils are shown in modern drawings of lightning protection, and I have and reviewed those of one the largest communication companies in the US.

Realistically, such a coil never had any chance of slowing down a 8us/20us or faster attachment of 100,000,000v or even a fraction of that in the smallest of strikes. Coax can only carry 4,500v before the dialectric breaks down and then your SWR and balanced currents are no longer part of the playing field. At about 5,500v the coax can no longer carry the energy by itself and will arc over to anything nearby. So diverting 99.9% of the energy via a fast acting suppressor and shield grounding is the only hope for coax which does in fact take an attachment. Most times the coax does NOT receive the direct attachment! So after shield grounding and arrestor connection, the coiling isn't necessary in the first place, would do no good, and can most certainly act as an air wound transformer to EMI if "wrapped in a dozen or more turns" as you said. Even one turn. Fortunately, coax is "resonant" (used only as an example for high-velocity and low impedance) to a fairly small portion of the DC and AC component of a direct attachment. Not so to the EMI near field, which any wire regardless of it's velocity or impedance will be subject to inductive coupling of EMI. The coax shield will absorb most of that EMI, and unless it exceeds 4500v (very possible in a 50 percentile strike) will be diverted harmlessly to any nearby shield ground. 12 turns of the coax shield - you do the math as you are an electrical engineering expert here - what's the voltage out from 4000v in? Yikes.

Art,

You've _talked_ about an antenna design which you claim does these
things. You have never, as far as I have seen, "described" it clearly
enough for anyone to actually draw a picture of it that you were
willing to agree was accurate, despite having been asked for this
detail a number of times.

Until you actually demonstrate it (so that it can be subjected to
unbiased tests), or succeed in describing it clearly and accurately
enough that someone else can reproduce it and test the reproduction.

Until you do one or the other, I'm afraid that I have no confidence
that your design does what you say it does, or works the way you say
that it works.

Sorry, guy. On this, I'm "from Missouri"... I say "show me!"

>Now David I know hams do not like to pursue the idea of maxcimum radiation

(sorry of this posts twice, ISP has newsgroup problems)

Hi Harry - well, the web is FULL of massive information, and the old trick
of coiling coax for lightning protection is simply not specified any longer.
I will look up the sites which warned against it, citing amplification of
EMI by such a manuever, and get back to you.

>
> First of all, it is the purpose the the coiled coax to act as an
> inductor (r.f. choke) because this is how it resists the very rapid

> power damage potential.

Arrestors AND shield grounding are specified at the TOP and BOTTOM of the towers, and AGAIN at the facility entrance. No coils are shown in modern drawings of lightning protection, and I have and reviewed those of one the largest communication companies in the US.

Realistically, such a coil never had any chance of slowing down a 8us/20us or faster attachment of 100,000,000v or even a fraction of that in the smallest of strikes. Coax can only carry 4,500v before the dialectric breaks down and then your SWR and balanced currents are no longer part of the playing field. At about 5,500v the coax can no longer carry the energy by itself and will arc over to anything nearby. So diverting 99.9% of the energy via a fast acting suppressor and shield grounding is the only hope for coax which does in fact take an attachment. Most times the coax does NOT receive the direct attachment! So after shield grounding and arrestor connection, the coiling isn't necessary in the first place, would do no good, and can most certainly act as an air wound transformer to EMI if "wrapped in a dozen or more turns" as you said. Even one turn. Fortunately, coax is "resonant" (used only as an example for high-velocity and low impedance) to a fairly small portion of the DC and AC component of a direct attachment. Not so to the EMI near field, which any wire regardless of it's velocity or impedance will be subject to inductive coupling of EMI. The coax shield will absorb most of that EMI, and unless it exceeds 4500v (very possible in a 50 percentile strike) will be diverted harmlessly to any nearby shield ground. 12 turns of the coax shield - you do the math as you are an electrical engineering expert here - what's the voltage out from 4000v in? Yikes.

You have a great installation - and adding a few ground rods and shield grounds will top it off. Stay tuned for the looping coax fiasco finale....

Jack

David I feel sure that the new design is what I have described and we will know in a few weeks.
But do yourself a favour and roughly model the following
which is not a final design.
Create a closed loop and divide it into 20 segments
and then cut it in half to make the program shorter.
You then place these haf loops at varying heights with a matter of inches between them. When they are connected
together starting from the ground the resulting patter will be a cloud warmer with high gain. This does not take long to do and if you scan frequencies you qill find the pattern change interesting. If you then become interest then connect the half loops instead of 1,2,3 vertically move the fthird loop to position one and so forth plus connect them so that you have both clockwise and counter clockwise
radiation, you will then see a flattening of radiation to the horizon.
Enough said, I am not interested in a verbal snotty battle which will surely happen now that Richard has entered the thread. If the new patent does not follow the scheme of things outlined then I will supply to you
a model and a picture of an actual antenna. So let us await the release of details of this new' revolutionary' antenna which I am sure that Chip will supply.
Cheers
Art

Hi Art,

I merely pointed out your antenna shows 17dB loss compared to the
standard antenna. Sorry if that rains on your parade.

I just assumed.....why should I spend all that 'quality time' on a modeling
program? If it will confirm what I know, or can find, in a decent antenna
book??

A ham friend bought this antenna. I checked his match with the antenna on the ground reflector down on plastic sawhorses 2 feet above ground and the director pointed to the sky. 10 and 15m matched just fine. 12 and 17 were ok but 20m was way out of match. We reduced the 1st and 3d element tips to 7 inches and have a good match at 14.100 but in the phone portion around 14.250 the match was 4.6:1. When at 8 inches the match was over 6. Does anyone have any experience with this antenna? I want to be cautious about cutting the tip portions of ele 1 and 3 so I can shorten the elements more and hopefully bring the antenna into proper swr range. The band width on 20 is only 90 kHz. Any help or comments would be helpful. BTW Cushcraft has not yet answered any of his calls.
tnx donald wk6q

Just going on what I have done, it is really interesting to model antennas
that I have have actually built, and see if the results agree with the model.
Mostly they do.
I have found that it is easier to model an antipacited design, and go through
the various iterations to see how it pans out.
It has been 4 years since I have built an antenna without modeling first
Antennas are fun, and cheap, at least wire is cheap

I suggest that before doing any more trimming that you do everything
possible to get this antenna higher up from the ground to take
readings and make adjustments. You may want to also keep the antenna
in the same orientation as it will be when installed. There may well
be other things in play with your antenna - but these two changes in
your process may help, it has for me in the past; I learned the hard
way and had to un-install the antennas from the roof & used a
temporary mast in the center of the backyard to 'tune & prune.'

Hope this helps,
Howard ke6mak

I remember something about that - now that you mention it - but there was
some drawback other than price - I think it was lossy - but I may be in
error - going by memory
I once had a good memory - but forget where I left it.

Message-ID: <411ad192$0$74193$39cecf19@news.twtelecom.net>
Source record: 91073

Here are the designs I said I'd send if requested. Bob requested, and I sent them to him via email. I am copying the email here with a little bit of editing, since I sent him 2 emails.

Here is the 4 element version. This one was designed to be stacked with 12 foot spacing, but still works fine as a single. The only thing that suffers is the rear end of the pattern gets the "butt cheeks" above 50.2 when not stacked.

The first column is the position on the boom, and the second is the 5/8's section length. The 3/4" center piece is still 48".

0.0000 35.4375
39.3750 34.1250
84.3750 31.1250
142.0000 29.2500

And here is the 5 element version, still on a 12 foot boom. This has never been built, but I've built enough of these from the YO models to know it should be just fine.

0.0000 35.8125
21.2500 34.1875
42.5000 31.0625
86.5000 30.5625
142.0000 29.6875

With both of these, matching is your own business. Impedance of each is roughly 17-j13. The A5 design shows about 32-j13, so you will certainly have to change the gamma arm length, but the capacitance close to the original. Worse comes to worse, drop me another note, and I'll send you the homebrew gamma design I have that matches easily.

The 5 element version has .2dB additional gain from the added element's weight.

Dr. Slick wrote:
"I`d like some advice on building the phasing harness required for the following antenna,"

The antenna described has one-wavelength spacing between antenna elements. As velocity in the coax is only about 2/3 that in free space, one-wavelength of phase delay in cable won`t stretch between the antenna bays as shown. Solution is to add another wavelength of phase shift to the interconnection cable or to simply use a pair of identical cables of almost any length to parallel the bays at a driving point. Any desired phase delay can be added to one or the other of the cables to shape the pattern.

Best regards, Richard Harrison, KB5WZI

This is probably not the right group for this question...but you guys
are the experts on antennas so I thought I would throw my question out
there...
I am in an office building (43rd floor) and I was wondering some tips
on getting television reception to come in clearer? I have a basic
bunny ears antenna but the picture is very fuzzy and fades...this is
almost certainly because of the building. Is there anything I can do
to make the picture come in clearer?
Thanks,
Nickolas

> I am looking for some advice on if the ground system featured below is
> sufficent or should be upgraded. It consists of:
>
> - 3 ground rods 10' each around the tower (bonded together)

Lightning likes to go straight. Try to have at least one ground rod connected to the tower base at the base; the rod should be directly under the base or as close to touching the base as possible. A 10' ground rod is good if in conductive earth. In sandy Florida, where I tood several hits, it took over a 20' length of ground rod (1/2" steel water pipe) to hit conductive "hard pan". I just washed it in until it hit some solid clay, and then washed it into the clay as far as I could.

> - 2 ground plates (one outside, one in the shack, also bonded
> together)
> - lightning arrestors and/or feedthrough adapters
> - tower to mast ground - interior coax switch (not shown)

The coax switch should be a grounding switch. Floating elements on an antenna could actally attract a lightning hit. Also, for induced hits (not a direct strike, but with enough voltage to damage equipment due to a nearby strike), the grounding of the antenna lines gives the charge a nice safe path to follow. That's better than letting the current find its own path by arcing somewhere. I like to turn off the AC power to my entire equipment setup when not in use. So, with the power switch on the transceiver and the main "shack" ac power switches off, a lightning surge on the power line can only get me or the equipment when I am actually operating. One last suggestion: put a big (3 or 4' diameter) vertical loop (preferably near the ground) in all tower cables going into the house. (Right over your ground plate might be a good place.) The inductance of the loop, and the fact that lighting likes to ionize paths in a more or less straight lines, will keep the main current surge of a direct hit from entering your house and finding its "home" in your power line or telephone line. I survived operating for many years in the lightning belt of Florida and have the burn marks on my mast to prove it. The only known damage in Florida was some induced power that killed a couple of ICs connected to a printer ribbon cable. That was just from the current going down the tower on the outside side of the wall. Lightning protection is still as much art as science, Lloyd - but what you have done so far should fairly well protect folks in the house. If lightning is going to hit, just let it find a nice safe home - and try not to be

operating when it does. HI HI

In Florida, a house one block from us burned to the ground when lightning started a fire in their attic. That couldn't have happened at our house, as the lighting had a 70' tower to hit first, and a 23' ground rod to give the current a safe place to go. We were hit - several times. So, look at your well grounded tower as an asset for true lightning protection - not a liability.

I have an ICOM-725 (HF system, 100W output) connected to a MFJ tuner and then about 120 foot feedline run to an antenna I made myself.

I can get the SWR on the MFJ tuner to read nearly 1:1, but the transmitter display shows only about a 25% power output.

It occurs to me that the impedence that the tuner is "seeing" is so high that the transmitter simply cannot supply the necessary current, i.e., as with any voltage source that gets swamped.

Make sense, or am I barking up the wrong tree?

Thanks.

Thomas

certainly... install an antenna on the roof and connect to TV.

oh.. i bet you did not want to hear that answer.

try some different things.

move the antennas near a window.

there are gizmos that you can buy which safely couples the antenna input to
the buildings AC wiring.

try an amplified indoor antenna.

Hi Lloyd,

Of the advice offered, out of the dozen or so comments, only the addition of radials and grounding of peripheral equipment made any sense to your already extensive installation. Adding "more" rods sounds like hail Mary solutions. I would bet almost every house for 10 miles around you survives quite well with one.

Sure, few if any sport towers, but lightning in the vicinity is not so choosy as to miss every house, building, or power pole simply because they are not radio amateurs.

I also note the complete absence of discussion about the Code. All grounds must be bonded (clamped, not screw attachment nor solder/brazed) with a continuous wire (no breaks or splices). I also note some rather bizarre descriptions of how chokes work (and to add that they are not used by Hams is simply ignorance or the choice to illustrate with poor examples).

I would suggest you mine the archives of rec.radio.amateur.antenna for two correspondents: Richard Harrison, KB5WZI for thousands of commercial and amateur tower installations over a career spanning 50 years (you will discover half to two thirds of suggested embellishments are immaterial fluff); and Reg Edwards, G4FGQ for the topic of successful ground rod application (notable in that laying them horizontal is just as good, if not better).

As to your last comment about getting fried. You should examine that illusion and recall that it brings voltage to mind, not current. Voltage comes from two mechanisms common here, impedance and resistance (the lightning strike is considered to be from a constant current generator willing to present any potential necessary to preserve flow). A sharp bend in a conductor is one source of impedance change for the bad - so graceful sweeps are preferred where

you want to change direction. I note the irony of discussion where chokes are used to build voltage (power being equal to Iï¿½E and current being constant guarantees a build up of power beyond what would have been suffered) to guarantee spark discharge elements firing (I suppose so, but this sounds like Advertising Copy to sell spark discharge elements). Most successful solutions offered here for years and years all have the common goal of burying the lightning stroke's current into the soil as soon as possible without any impedance to its path. If you research the archives for low resistance paths of lightning, you will find out how little total power is suffered in a strike (don't fall for the monster under the bed stories of a gazillion volts at a bajillion amps).

Invariably when antenna gain is mentioned
questions arise as to gain measurement and accuracy there of.
I do a lot of antenna experiments and declarations of gain never get
any where.
Ihave now purchased a 27 Mhz electric model airoplane and am now in
the process of making a new design antenna and I intend to measure an
antennas
relative gain my comparing the distance travelled by the model by
usind a standard whip antenna and then by using newly designed
antenna.
I visualise keeping a record of distance travelled of my various
experiment antennas.
Does any body see any negatives about this aproach which will always
be done under zero wind conditions? I am looking for a real world
guide to gain to escape from the gain arguments of today.
Thanks in advance
Art

1665. Re: Grounding Tower & Shack (Advice Needed)

Having read the various post concerning coiling the coax to form a "choke", I recall a technical article from "PolyPhaser.com", the lightning product company. Below is an exerpt from the technical document covering Amateur Radio lightning protection and coiling of coax cable to form a choke.

Quote:
(from www.polyphaser.com website)

Document Number PEN1016: An overview of Lightning Protection for Ham Radio Stations

Even though the inductive properties of the coax cable appear to be beneficial, and extra inductance can be created by adding a few turns to the coax; don't do it. The added turns can also act like an air wound transformer coupling more energy into the line. Make sure coax lines leaving the tower remain at right angles to the magnetic field surrounding the tower.

Unquote

It is my belief, based on coils and induced energy into the coil, that coiling of the coax will induce an EMF field that can be picked up by the coax, or other cabling, allowing it to enter into the house/shack or, more simplified, follow a path that is not desired, i.e. the coax or rotor cable run to the shack. Grounding of the coax at the top and bottom of the tower, attaching coax lightning protecting products at the base of the tower and running the remaining coax to the shack through buried metal conduit, greatly reduces the chances of lightning strike energy from entering into the cable(s) leading from the tower. Additionally, each leg of the tower, not just one leg, should be grounded through it's own seperate ground rod and each leg ground should be connected to a circular grounding system, around the tower. The tower grounding system should be further connected to a house grounding system surrounding the house with 8 foot grounding rods driven into the ground and connected to the house grounding system (central point grounding). The tower grounding system along with the house grounding system should be connected together. The distance between the tower and the house/shack can be lengthy. Connect the 2 systems together and add additional 8 foot grounding rods every 16 feet along it's path.

Using buired conduit for coax and rotor cable, for example, greatly reduces the chance of EMF fields from flowing along the coax and into the shack. A direct lightning strike to the tower will generate an EMF magnetic field that can be picked up by coax, rotor and coax switch cables then flow into the house and through the equipment and/or wiring. The tower, during a direct strike, radiate a large EMF magnetic field that can be picked up by

anything within it's path. The strength of the field reduces by a factor of
1, outlined in the Polyphaser.com technical document.

Just some technical information I've found from lightning protection
companies during my search for documentation on tower, antenna, coax and
rotor cable installation.

73's,

Mike

How can you know the exact distance the receiver is from
the transmitter? 73, Cecil

1667. Dead Serious T2FD: HV Insulation, EMP Arrestors, extra Coax Choke?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-12 17:51:52 UTC
From: n1jpr@hotmail.com
Message-ID: <95a201e0.0408120951.21b40722@posting.google.com>
Source record: 91088

As the T2FD is growing in popularity,
I hope these issues will be of interest
to more than just a few.

SITUATION

I. I am building a T2FD, for receiving and *maximum* 10W RF out.

II. I have a decent RF and DC ground near the antenna site on top of the building (huge masses of steel), but not in my shack, which is some 120 ft. below. This is not unlike having the antenna out on the lot, and the shack somewhere up in the attic.

III. I want to get rid of any static charges and also to reduce the risk of EMP travelling down the coax. This too must be a concern for quite a few people...

IV. Also, I'd like to avoid as much as possible any hums that may derive from poor double grounding. After all, we mostly do HAVE to ground stuff inside the shack as well, for electrical safety.

PLAN

1) Make the balun with full DC-insulation between high-Z and low-Z windings on the toroid-core balun. If everything is nice and symmetric, only transversal-mode RF will flow.

2) Ground the middle of the high-Z winding to the locally available ground. NOT ground the low-Z winding - I'll just connect it to the coax. Route internal wires for maximum insulation. Fill the balun case with either epoxy or urethane foam. Keep the two leads (coax, ground) well separated.

3) Insert EMP dischargers right into the balun:
- One across the high-Z winding, for transversal mode.
- One between each high-Z lead and ground, for common mode.
- One across the low-Z winding, a'shunt the coax, for transversal-mode.
And also one across the top resistor, also for transversal.

4) Put one or more large iron-core chokes on the coax, as to dampen EMP that could possibly travel on the outside of the coax shield. (This would also ensure that RF power or noise will not travel on the outside of the shield, of course)

LIFE IS FULL OF QUESTIONS
Here are just some of mine.

a) For HV DC insulation in the balun, I intend to use as large a PVC-insulated conductor as I can fit, wind the high-Z winding, wrap it in insulating tape, and wind the low-Z winding on the top of the insulating layer.
- PVC is said to be lossy. Is it a dramatic loss or not?
- What tape should I use?
- Is the insulated core of a coax a decent alternative to HV wire?
- What is the implication of making a low-Z winding ATOP the high-Z one & the insulating layer, instead of interleaving them?

b) For receiving, small 90V neon bulbs should already provide some protection. But 10W RF on 75 ohm already means some 27+ Vrms, wich would rise to over 50Vrms across a balanced 300 ohm load - if the mismatch is modest, that is.
- Are low voltage neons already sufficiently horourable dischargers, or should I consider some other kind of (comparatively more honourable) dischargers?

c) For the coax shield choke, I am considering 20 tight turns on a 5in. plastic pipe, the steel core being made with pieces of thin, insulated rebar - enough to fill the pipe. The core should increase the inductance considerably. Weight not an issue: the choke will be hung somewhere safe on the roof, probably 40 ft. away from the balun.
- Any reason to vote for either major party candidate in the coming election?
- Any reason to use FLAT steel instead of cheap, easy to find rebars?

d) Other than the difference in weight, what are the pros and cons of potting a balun in liquid-poured epoxy resin vs. filling the balun case with urethane foam injected from a can?

Any contributed wisdom will be appreciated!

My ISO Loop antenna needs a new gear. It is the gear that attaches to the capacitor tuning part.

Any ideas on where I might get a part? AEA is out of business.

Two ways:
1. Use an autoresponder and measure the round trip propagation time
(of the last transmission) - this is probably the most accurate;
B. Set the trip meter on your car when you go to find the fallen
airplane (taking care to subtract out all meanders and any excess fuel
that added to the airplane flying out beyond the reception zone);
III. Employ military grade optical range finder to track airplane and
use a transmit signal to inhibit the plane's light strobe - when the
strobe goes on to denote lack of signal strength, then take visual
range reading. For poor antennas, a camera grade range finder may
work just as well;
2ï¿½. Use the old V-1 Buzz Bomb patent log system of a small propeller
geared to indicated travel distance driving a mechanism with voice
synthesis to announce that distance until it can no longer hear the
base station.

There are probably at least two more ways.

Hi Art,

I missed the part about this being an "electric" airplane. So, the
plan is for a sort of squelch controlled (supressed) air brake of a
sort, Hmm? What about if the battery runs out before the signal
(false negative)? Get a bigger airplane (battery) I suppose. You
might want to consider that the airplane has advantages of
line-of-sight which means you could contact it for hundreds of miles,
if only you could get it high enough. If you can't, you may as well
ask a ham across the city what you are reading on his S-meter.

Nope, they were range set against a count down counter that was driven
by a patent log mechanism (boats use this everyday as a taffrail log
or a screw log).

> If Churchill had council to

You would also need some precision receivers for even those worthless
antennas. For 10M operating out to 200M, only 20 wavelengths, that is
hardly any signal strength change to speak of and to make the plane
dive at some pre-determined signal level is going to take quite a
sophisticated measurement. Keep in mind that neighboring interstate
CB traffic is going to mix in and muddy up the response (your airplane
may follow the next Coke truck to Chicago).

1676. Resonant frequency

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-12 19:43:49 UTC
From: Dave VanHorn <dvanhorn@cedar.net>
Message-ID: <u6udnXnHTJvwVYbcRVn-rw@comcast.com>
Source record: 91097

I'm having a bit of a difficult time with analyzing this circut:
http://www.dvanhorn.org/TankCkt.gif

This is an oscillator tank, where C2 and L2 are parallel resonant.
The operating frequency is around 280kHz, with C2 at 3300pF and L2 at 98uH.
The interesting part is where I add L1 at about 40mH and Cg at 0-1pF with
Ctrim at some small but significant value. (ideally, series resonant at
about 290 kHz, but you have to take parasitics into account)

What I'm trying to do, is to determine the oscillating frequency as Cg
changes, and also to evaluate different values of L1 as the series resonance
of L1/Ctrim+Cg moves around the tank resonance. Obviously if the two
resonances collide, it's not nice.

I'm having a hard time finding how to express the change in Cg as a shift in
the resonant point of the oscillator tank.

The formulas that I have for impedance show only the magnitude of the
impedance, and probably aren't applicable to this situation. Where can I
find a better approach for analysis?

Once I have this down, I have to consider the parasitics and series
resistance, especially in L1 which are pretty significant, but I have a
handle on how to apply that.

YIKES! You haven't flown one yet??

Flying AND doing some kind of signal measurement??? Your idea of a time-travel transponder is a good one. Me thinkth that you will be spending a long time learning to fly and building all the other equipment before you get to do any measurements

I don't know what you have, but the regular (the 'good' stuff) R/C equipment has a range exceeding one mile or 1.6 Km. This is much farther than you will be able to see it. There are add-on accessories which will cause something to happen when the transmitter disappears, but without one of these, they can simply continue flying until the motor runs out. it may or may not turn or descend until then depending upon what the controls were doing just before the signal died.

In the US, 27 MHz is a hazardous frequency to be on...don't know about elsewhere. Good units are in the 75 MHz range.

Then you have to fly in the far-field, right?

...good luck.

I think I'd find a pilot (my son) and fly around with a receiver...

If you're trying to trip something at a specific point, you might try using
a different WWII technique, scaled up. They did bomb releases by flying
till they crossed a radio beam.
You could use a microwave (10-24 GHz) source as your beam transmitter.

Later systems used two beams, and more sophisticated means.

Measuring absolute signal strength, at any real distance, is going to have
such huge variability as to make it useless.

If an anteena has a specific range dominated by its power input and a distance thru air would not a ntenna with more gain allow it to0 travel a longer distance until the plane
came to a distance to allow a relay to drop out.
I was looking for a meaningfull indication of gain that would not be assaulted gurus negatives with respect to isentropic gain and disbelief of calculations made.
What better way for the man in the street to understand antenna gain rather than messing with dbi, dbd e.t.c., which an amateur uses to fulfill his need for conflict?

Art

If I'd be allowed to change my mind after I got more thought/information
on this project, I really like the idea. It will be somewhat of an
instrument complex project ?wont it?.
A GPS could record alot of data if the plan includes things like that.
I would have thought that small variations in distance to the aircraft
wouldnt be excessively critical. But, it would be important to keep
records of the angle to the aircraft from the antenna.
I see Excel and some clocks somewhere in there.

This sure would be a fun project. If you do get it working, I'd go to
where you are just to see it in action.

Jerry

If you were able to place both the transmitter, and the plane in free space, and there weren't other signal sources in the area, this approach might work out.

In practice, though, I think you're going to find multipath and reflections to be a real problem. Irregularities in the ground, the presence of buildings and trees, etc. are going to generate enough reflections to cause some serious, and unpredictable changes in the signal strength as seen by the receiver in the plane.

De-sensing of the receiver by transmitters on nearby frequencies, noise pickup, directional variations in the plane receiver's antenna, etc. are also going to be problems. I think you'll need a fairly narrow-band receiver, with a well-controlled and fixed gain and a wide dynamic range, and some form of averaging circuitry to get you past the multipath / picket-fence problems.

I'm sure that something like this _can_ be done, and can probably be done well enough to result in meaningful measurements. To do so, I think you're going to have to invest a good deal of time, energy, thought, and perhaps money in the design. A poorly-designed approach would introduce so many sources of possible error that any results you got from it would not be particularly meaningful or significant.

>I was looking for a meaningfull indication of gain that would not be
>assaulted gurus negatives with respect to isentropic gain and disbelief of
>calculations made.

I'd suggest studying how this sort of measurement is performed in a professional context - e.g. on antenna ranges located out in the country well away from strong RF sources, and in shielded RF-anechoic chambers (for near-field measurements and for higher frequency measurements, where the chamber is a reasonable number of wavelengths across).

>What better way for the man in the street to understand antenna gain rather
>than messing with dbi, dbd e.t.c., which an amateur uses to fulfill his need
>for conflict?

Please don't confuse "conflict" with "criticism". The former is unnecessary (although unfortunately it's rather common). The latter is utterly necessary in any form of scientific endeavor!

Cross-posted to: rec.radio,rec.radio.amateur,rec.radio.amateur.antenna

Reasons not to create a coiled-coax "choke"

http://www.comm-omni.com/polyweb/hamradio5.htm
Even though inductive properties of the coax cable appear to be
beneficial, and some extra inductance can be created by adding
a few turns to the coax; don' t do it. The added turns can also
act like an air wound transformer that can couple more energy
into the line. This is just the opposite of the desired effect.
Instead, make sure that coax lines leaving the tower remain at
right angles to the magnetic field surrounding the tower.

http://www.wrblock.com/Papers/Amatuer_Radio/APARS_P09.htm
Neatness counts - cables (transmission lines, power (ac and dc),
speaker, microphone, computer, control) should be cut to length
and routed neatly and cleanly between boxes using the most direct
practical route. The coiling of excess cable length on the
protected side should be avoided since it could act as an air-wound
transformer coupling magnetic energy from a nearby lightning strike
back into the protected equipment.

http://www.marcspages.co.uk/tech/2100.htm
Some in the RF industry would have seen coils used as static drains.
The theory is the coil is high impedance at RF and so looks open
circuit, whilst still presenting a short to the DC and draining it
to deck. The problem with them is they too can start reacting
('scuse the pun!) with the capacitance present on the system,
especially at the lower ends of the band.

24hr ops FULL COVERAGE PROTECTION (no "chokes")
http://users.erols.com/n3rr/lightningprotection/

http://www.alvarion.com/RunTime/Materials/PDFFiles/Lightning_Protection_White_Paper_March3
1_R41.pdf
ALVIRON SUBSCRIBER SYSTEMS TOWER LIGHTNING PROTECTION
(no "chokes")

And one major US communications company which drawings and specs
are confidential and proprietary information - but they do NOT use
any kind of coiled-coax and prohibit same from all systems.

Here's one exception - from an Amplifier and relay company - they
are NOT in the lightning protecton business and this is very
outdated advice, but shown anyway becasue we're honest!

http://www.ameritron.com/ameritron/man/pdf/RCS-4.pdf

We strongly recommend the use of lightning retarding loops
in the coaxial cables near the relay box (see illustration).
Remember that lightning travels through the path of least
resistance. Station ground leads should be solid, large surface
area conductors. Do not use braided or stranded wire for the
ground leads. Avoid sharp bends in the ground leads. Use
multiple ground rods and/or radials to provide the earth
termination.

Recommend you ignore this and maintain direct paths - JP

Finally, Richard Clark's mention of "code" is pretty important. Reference
the NEC-70 and NFPA-780 for US installations.

It might help if you told what you are ultimately trying to do.
Is this just a thought experiment designed to help you learn something?
Is it a circuit you have/see and are trying to understand it?
That antenna is an unknowns, as well, which I guess you are ignoring...?
From what I see/read, you are trying to do something which is very
awkward...that is, multiple coupled resonances.

Looks like you want to see what kind of "pulling" effect the Delta Cg is
going to have on your oscillator. Why inductive coupling?
The conditions which determine the frequency of oscillation are not confined
to the resonant frequency of your tank, but include phase and gain of the
active device as well.

I modeled a 1 MHz Colpitts in PSpice and it oscillated nicely. Adding other stuff to muck about with it could be done...

Source record: 91104

How about if you get a field strength meter and walk away from the reference antenna (like a vertical 1/4-wave) until you get a mid-range reading. - then do the same with the tested antenna.
compare the distances - and note that signal strength is inversly related to the square of the distance.
If the distance for the same reading is double for the beam - that means it has 4 times the effective power in that direction.
then convert to db-gain

Yes, after a fashion. What you mean to say is you are still far from
earth ground, but have plenty of metal.

>III. I want to get rid of any static charges and also to reduce the
>risk of EMP travelling down the coax. This too must be a concern for
>quite a few people...

Certainly are for those who aren't signatories of the Nuclear Test Ban
Treaty.

>IV. Also, I'd like to avoid as much as possible any hums that may
>derive from poor double grounding. After all, we mostly do HAVE to
>ground stuff inside the shack as well, for electrical safety.

Anticipating what follows, perhaps you should simply loop couple all
of that steel at the top of the building. No ground issue there. No
direct connections. No HV problems.

>
>PLAN
>
>1) Make the balun with full DC-insulation between high-Z and low-Z
>windings on the toroid-core balun. If everything is nice and
>symmetric, only transversal-mode RF will flow.

If you do it right - maybe.

>2) Ground the middle of the high-Z winding to the locally available
>ground. NOT ground the low-Z winding - I'll just connect it to the

>coax.

Here is where the part about doing it right raises its ugly head.
Ground is not simply a matter of being bulk metal. At least not RF
ground, and not always safety ground.

>Route internal wires for maximum insulation. Fill the balun
>case with either epoxy or urethane foam. Keep the two leads (coax,
>ground) well separated.

This is more a matter of cosmetics and personal preference than
engineering consideration. Lead dressing is adequate and mounting
does the rest.

>3) Insert EMP dischargers right into the balun:
>- One across the high-Z winding, for transversal mode.
>- One between each high-Z lead and ground, for common mode.
>- One across the low-Z winding, a'shunt the coax, for
>transversal-mode.
>And also one across the top resistor, also for transversal.

The resistor is already going to snub any "EMP" the rest is window
dressing. It takes quite a few KV to jump an inch.

>4) Put one or more large iron-core chokes on the coax, as to dampen
>EMP that could possibly travel on the outside of the coax shield.
>(This would also ensure that RF power or noise will not travel on the
>outside of the shield, of course)

8 turns of 6 inch diameter loops will do just as well, as would a
simple 1:1 Current BalUn. You are too much concerned with Nuclear
Blast. If you suffer EMP, you've got far more to worry about.

>LIFE IS FULL OF QUESTIONS
>Here are just some of mine.
>
>a) For HV DC insulation in the balun, I intend to use as large a

>- What tape should I use?
>- Is the insulated core of a coax a decent alternative to HV wire?
>- What is the implication of making a low-Z winding ATOP the high-Z
>one & the insulating layer, instead of interleaving them?

10W is not going to generate any potentials to offer such prospects of
arc or corona - unless you are constructing a very small loop or
dipole. You have already described you are using a T2FD which
obviates that headache.

>b) For receiving, small 90V neon bulbs should already provide some
>protection.

And maximum noise generation if they should ever fire. How's that going to happen? Is this massive metal structure at the top of your building an AM transmitter tower with a 50KW signal?

Believe it or not, some Neon bulbs will not fire if they are in the dark (you can certainly force the issue - so I guess EMP will satisfy that in spades).

> But 10W RF on 75 ohm already means some 27+ Vrms, wich

Hi OM,

I can only guess this is all about lightning, but you have far more interesting possibilities with the coax drop to your apartment brightening up your bedroom. In fact, you would probably get just as good a signal out if you simply ran 20 feet of coax to a 100 foot wire going up and tying off (or not) to all this metal.

Basically, there is nothing T2FD about your post whatever. Why don't you start over with what you are worried about instead. For one, explain just what EMP means to you.

Bought it on EBAY fgor $25 shipping included Now
camera type transmission to receiver is about 200 feet max so I do not
expect to be anywhere in the range that you state. Equipment built ready to
go. Keep it in your mind that the engines are driven by batterries and is
not the expensive motor type. Big difference.

Jerry, in the Midwest we have a lot of flat lands with corn and soya beens
so it is very easy to find a place to test after the harvest. Watched
somebody operate one of these and I wopuld expect that you would take an
average of say 5 flights each before the battery die.
One may see reflections off of a corn cob that has not been gleaned. 27 Mhz
was not my frequency of choice but this was available. Planes are two engine
type and are controlled by turning the motors on or off for turns.....
no flap movements....very simple I would think that doing a distance
comparison is more believable when seen than any manufacturers specs and
would give me sufficient
guidance when an improvement occurs. I certainly think it would add
crededance when observed at a club meeting
even tho gurus with a little bit of knoweledge will require more
sophisticated equipment. If I was comparing one
manufacturer to another with respect to
R/C controlled equipment it sure would satisfy me as seeing is believing .
When I asked for comment I had already put in place all the good things
and it was my expectations that the group would focus on the negatives
which is how it came out with a balancing list of negatives to compare
Appreciate the comments

Running into a 50 ohm dummy load allows full transmitter output.

Yes, the IC-725 power output know was fully clockwise.

When connected to the antenna the IC-725 indicates 25 - 50% power (not much needle deflection difference between the two) and the tuner power meter indicates in the 25W to 50W range.

So it works into the the dummy load, next steps?

Thanks.

Thomas

Art

If the goal is to compare the signal strength of an antenna under test,
with the signal strength from a standard antenna, like a quarter wave
vertical, I'd think this aircraft method would provide decent information.
I do think there is no way to determine the performance of the 'antenna
under test' so the antenna design community could accept the data. But, it
would be a valid comparison of any antenna with a standard antenna. That
would be a "specific antenna gain".
How would you sense the variation in signal strength received at the
aircraft?

Jerry

> It might help if you told what you are ultimately trying to do.
> Is this just a thought experiment designed to help you learn something?
> Is it a circuit you have/see and are trying to understand it?

I have several schematics (all roughly similar), and a couple physical
items.
I'm trying to understand the interactions, and what all the variables are.
It's hard to explain in concise terms.

I've modeled the effect of Cg on the tank directly, that's easy, and the
effect is rather small.
Adding the series inductor makes a large and desirable change.

> That antenna is an unknowns, as well, which I guess you are ignoring...?
No, that's part of Cg. I am approximating it's capacitance based on it's
surface area, using the formula for the capacitance of a sphere. I know
it's not a sphere, but I have yet to see a formula for the capacitance of a
rod in space. That's a starting point anyway.

> From what I see/read, you are trying to do something which is very
> awkward...that is, multiple coupled resonances.

It does seem awkward, but there are interesting things going on here.

> Looks like you want to see what kind of "pulling" effect the Delta Cg is
> going to have on your oscillator. Why inductive coupling?

It appears that the inductor amplifies the effect of Cg.

Right.

> I modeled a 1 MHz Colpitts in PSpice and it oscillated nicely. Adding

I've not tried this in spice yet., I suppose that's an option.

Would not distance resolve that with the battery fully charged. Is not that the same when using a strength meter?I think Cecil should consider something like this for the 'shoot out' so as to advertise amateur radio and let the wives know what is going on. Perhaps try this at Las Vegas (check for insurgents and RPGs ofcourse)
I am sure that Cecil has the know how to smooth out the rough edges.

Oh Yeah -- Now I see the reason for refering to V2 flying bombs.
I was thinking there was an effort to fly the aircraft at and around
certain spots in the sky.

I think I could benefit from taking one of those *reading courses* I hear
advertized.

I am presently using a NOAA satellite and an S-Meter for my pattern range
at 137 MHz. I'm trying to synchronize Excel with the satellite position
right now. I dont propose that this experiment of mine has any practical
value.

Jerry

1697. Problem with Gamma Match?

Newsgroup: rec.radio.amateur.antenna

I'm having a problem with a 10-element Coushcraft yagi for 2m. I put the analyzer on it and its reading high SWR. I have tried moving it around, changing coax, etc in order to try and get something to change but I have not been able to isolate the problem.

I'm convinced the RF is being reflected at the antenna itself and not in the coax or other connections leading up to the gamma match. Looking for recomendations on what I could do to fix this thing. Its a pretty old antenna that has set out for a long time.

Thanks,

Jason

>rod in space.

Hi Dave,

That is not particularly hard if you have mathematical software like Mathcad. You simply do it "by parts." That is reduce the cylinder to a sheet 1mm tall and figure its surface area (pi ï¿½ D ï¿½ mmï¿½). This will be a constant value. Iterate that value over succeedingly remote distances from an infinite conducting plane. Add up all the iterations. (This is simply the integral of the capacitance formula for dz where z varies from an initial separation to a value equal to the height - 1mm.) For capacitors, capacitance is always described by the smallest plate so this is an accurate first pass approximation.

For instance (forgive the mix of units) a 1" thick rod, 9.4M tall, standing 10mm off of ground presents a 0Hz capacitance of 5pF. You could move it closer to ground (1mm) and raise this to 7pF, or you could lop off 8 meters and lower it to 3pF (not much variation).

However (and this is one of those points so ill-treated in this group) you cannot treat this capacitance as an equivalent capacitor for RF. The real component is much too big and this violates the first principles of Kirchhoff's requirements that physical dimensions must be extremely short with comparison to wavelength. The last time this one got wrapped around the axle was over the issue of lumped impedances.

The antenna may present any complex value of reactance to its terminals, including capacitances that belie this simple first pass analysis above. This, I doubt, is something that SPICE is sophisticated enough to deal with, as it also expects all lumped components and circuits to exist within very small dimensions relative to the wavelengths being supported.

Time to break out that XXth century museum piece, the Smith Chart.

>So it works into the the dummy load, next steps?

Hi Thomas,

Add a choke at the load (the antenna). Foldback of power, even in the face of 1:1 SWR, is suggestive of poor transmission line decoupling. One test is to vary the length of the line. If the SWR changes, this is a certain indicator of the problem.

No the V2s were a totally different thing. That was the sequel to Big Bertha
that shelled England from France
The V2 was a true rocket and I swear that I heard two bangs when they
landed, one when they hit the ground and 2 when it exploded. Either way it
was satisfying to hear as you then knew then thatyou were not dead, tho many
on this newsgroup would maintain that brain damage did occur

If it were on a copper plane, it would typically be about 4' from the plane.

Well, it's certainly not going to work with the flat plate close spacing
model.

Later, I want to look at the effects that happen if the cylinder isn't
circular, when the hand is very close, as opposed to say 10's of diameters
away. I do think that carving it into pieces might get to a pretty good
approximation ala FEA.

> Time to break out that XXth century museum piece, the Smith Chart.

Hmm.. I just picked up a smith chart implementation in mathcad.

Jason,

I have the same antenna, and had the same problem. Turned out to be the coax connector (SO239?) that connects to the gamma match. It is not well fastened to the angle bracket, and was not making good contact, even though it looked OK. To make it worse, it is screwed into the bracket from the back side. When you tighten the plug, you are turning it in the direction to loosen the socket. If mine acts up again, I am going to replace it with the connector that mounts with 4 screws,

Hi Dave,

Shape will probably have very little to do with it. If anything, the
computation by parts reveals that the last 90% of the rod is more or
less superfluous to the total value (at least for my example).

1709. Ring-and-stub antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-13 02:51:24 UTC
From: "J. McLaughlin" <JCM@Power-Net.Net>
Message-ID: <10hob3rbg2kcad2@corp.supernews.com>
Source record: 91030

Two bays, well above ground, fed in the middle is about as good as can be done. That is essentially what anonymous said. --- coax to a T and equal runs from the T to identical elements ---

[Note that using this scheme with identical HF antennas that are not many WLs above ground, will not optimize performance.]

As pointed out in a recent thread, the ring-and-stub antenna is sensitive to small changes in dimensions. [very sensitive] If the antenna is to be designed to be used where it is desired to have the free-space vertical and horizontal patterns be close to each other (in the horizontal plane), as in licensed broadcast applications, expect a lot of tweaking.

On the other hand, if it is not important to "balance" the patterns, most any balanced feed system will work to produce most of the gain near the horizontal plane.

Recently, I was faced with the issue of finding an optimum spacing of such an array from the face of a solid tower with a diameter of about 0.1 wave lengths. No hope, of course, in having the same real world vertical and horizontal patterns. However, it was possible to find a spacing that tailored the two patterns to an acceptable degree. The modeling needed a very large number of segments!

For amateur use, just space the phase center of the most important part of the antenna the magic 0.3 wave lengths from the tower surface and point the antenna in the most desired direction. Fortunately, because the most common amateur use is probably in conjunction with a repeater, one would be advised to use good old reliable vertical dipoles as the elements.

In short, in my opinion, you need to have a mighty good reason to deal with ring-and-stub antennas. For amateur use, better options exist.

Trying actual hardware, the last 1/8 inch is very significant, shifting the oscillator several hundred Hz.

Theoretically, common-mode currents can cause
weird problems like this one. It's possible that
common-mode currents are causing an erroneous SWR meter
reading and the differential SWR is not actually 1:1.
Does the SWR meter reading change when you touch the
tuner chassis or run your hand up and down the coax?

Your knoweledge exceeds mine on this subject
The instructions say it can take of and also land on at from hard surfaces.
With two engines being in the contol positions of either on or off it would
suggest that without power the plane will "glide" to a landing. this gliding
after exceeding transmitter range does present distance measurement
problems. Perhaps if the plane was weighted the landing could be more
"precise" as you say
but short of a "crash"
Seems like toys holds interests of every one .

>
> Yes, after a fashion. What you mean to say is you are still far from
> earth ground, but have plenty of metal.

Yes, it sounds weird, because it is. I have to thank another ham,
I2FZX, for the almost ideal situation.

On the TOP of my building there's a 50 ft steel lattice tower
(HF/VHF/UHF beams) and a tornado-proof 20 ft dish (1/2 kW UHF
moonbounce). They are some 80ft apart, both grounded.

Right now, I still have no real grounding in my flat - I just have a
virtual ground connecting all the conductive material in the shack,
which does help reduce noise and hazards. I intend to at least bring
the wiring up to regulation. That won't help with lightning safety,
though.

I intend to string the T2FD between the fixed part of the tower
(~40ft) and the base of the dish. I could use either for grounding,
but I'd opt for grounding at the dish, which is right atop my place.

>> EMP
> Certainly are for those who aren't signatories of the
> Nuclear Test Ban Treaty.

This is a bad neighborhood. Nuke blasts are an almost daily
occurence. As they are not meant for testing purposes, I am afraid the
NTB treaty does not apply. Also, there's a known focus of Al Qaeda
activity just a mile away (go to www.tuttocitta.it and plonk in Milano
/ Viale Jenner 50) but it can't be closed because it would hurt
certain people's sensitivities. I wear lead pants all the time.

> >coax.
>
> Here is where the part about doing it right raises its ugly head.
> Ground is not simply a matter of being bulk metal. At least not RF
> ground, and not always safety ground.

Well, not exactly.

A large bulk of metal is usually a pretty good capacitive sink at HF. In fact, even an insulated structure works decently as a RF ground. I even built crystal radios in which very few square inches of sheet metal were enough to provide a cap sink that had a large effect when worked against a wire antenna.

As for safety ground, NEVER "assume" that a bulk of metal is grounded. If you did, you could easily be found guilty of manslaughter in court. In some jurisdictions you have to get an an electrician to sign you off that, among other things, a piece of eqpt is properly grounded.

In professional radio installations, one sees a "ground reference" system which is indeed DC-grounded, but for RF purposes, most of the sink effect comes from strapping together everything in sight, including cabinets, metal furniture, building structures, drains, floor support etc etc.

> >Route internal wires for maximum insulation. Fill the balun
> >case with either epoxy or urethane foam. Keep the two leads (coax,
> >ground) well separated.
>
> This is more a matter of cosmetics and personal preference than
> engineering consideration.

I would like to maximize the chance that any burst of energy will take the ground path rather than the coax path. Why should putting, say, 3kV insulation between the antenna and the coax not matter? Incidentally, you do find kV-range insulation in commercial products as well.

> Lead dressing is adequate and mounting

So it snubs any EMP but not an RF signal. What is the spectrum of an
EMP? Is it more like DC or more like all across the RF spectrum?

> >4) Put one or more large iron-core chokes on the coax, as to dampen

Now I understand. FYI, what gets you in a lightning near-hit _is_ an
EMP.

I once had an audible arc in an antenna due to a 1-lightning
thunderstorm. That single hit happened in the midst of a city, and
took out several power stations and countless other equipment. My
antenna was 8 miles away.

Great! But what about losses?

I NEVER saw baluns with windings atop each other
- they were always directly wound on the core.
And I don't know why.

> >b) For receiving, small 90V neon bulbs should already provide some

Nothing but EMP. Lightning arrestors, if not MOV, are mostly gas discharge devices. All of yesteryear's professional toob radios and many consumer ones included a tiny neon lamp in their front end.

Great! But lead will lead to lead poisoning litigation too.

I don't want to litigate a lead-poisoned nuclear-armed jihadi.

Lead poisoning is also rumored to lead people to insanity
- see Goya (the painter, not the beans).

So, I don't want to litigate a lead-poisoned nuclear-armed totally-out-of-his-mind jihadi either.

I had thought about that too, esp. for LF! Problem is, between moi and the warship up on top lie crouching and waiting a few tens of TV sets and just as many PCs. I already have a wire going up to the 5th floor (out of 9). Works great, but only after 1 am, and only because energy-conscious Italians always switch off their gear at night.

I went to one of the local electrical supply places (where the electrical contractors buy their stuff) and found them quite willing to sell me high-quality ground rods, wire in bulk, PVC conduit for underground cable runs, etc.

I bought 1500 ft. of #12 black insulated solid wire for a very reasonable price. (I'm putting down 32 33ft. radials for a 5BTV, with a ground plate from DX Engineering.)

Check around ... not all of the large distributors will sell to the public, but many will - at wholesale prices.

73,
Carl - wk3c

Well, let's put some closure to this thing called ground. For much of discussion, ground is actually a large pool of excess charge that is highly mobile. That is, you can draw on its charge without significantly polarizing it. When you can't, you get electrical discharges (ground under a threatening sky becomes polarized and lightning occurs). In some sense, the bulk of this metal satifies this criteria, in other senses it does not.

Insofar as RF ground, anything, even earth, which is a signficant distance (in terms of wavelength) away presents a situation in which it is isolated and a problematic reference. In this situation, you can conspire through tuning mechanisms to optimize that path to be a good conductor (series resonate the lead going there); this works for RF but for lightning that is another matter (and at different frequencies simultaneously).

>I intend to string the T2FD between the fixed part of the tower

Your need for ground when you are using a dipole is unwaranted in terms of RF. Where would you connect it anyway? A dipole, by definition is self complimentary. However, the surrounding metal is certainly a disturbance to the self. Make sure the ends stand off from the supports by a good amount - I can only guess, and that would be 10 feet.

Well, let's put some closure to this thing called ground. For much of discussion, ground is actually a large pool of excess charge that is highly mobile. That is, you can draw on its charge without significantly polarizing it. When you can't, you get electrical discharges (ground under a threatening sky becomes polarized and lightning occurs). In some sense, the bulk of this metal satisfies this criteria, in other senses it does not.

Insofar as RF ground, anything, even earth, which is a significant distance (in terms of wavelength) away presents a situation in which it is isolated and a problematic reference. In this situation, you can conspire through tuning mechanisms to optimize that path to be a good conductor (series resonate the lead going there); this works for RF but for lightning that is another matter (and at different frequencies simultaneously).

>I intend to string the T2FD between the fixed part of the tower
>(~40ft) and the base of the dish. I could use either for grounding,
>but I'd opt for grounding at the dish, which is right atop my place.

Your need for ground when you are using a dipole is unwarranted in terms of RF. Where would you connect it anyway? A dipole, by definition is self complimentary. However, the surrounding metal is certainly a disturbance to the self. Make sure the ends stand off from the supports by a good amount - I can only guess, and that would be 10 feet.

Now, down in the shack you still have the same problem of ground being far away in terms of wavelength for RF. However, you are still using a dipole and the dipole is going to force its own relationships with the nearby structures. Presumably the T2FD will smooth out those wrinkles. Insofar as safety ground goes, it is hard to believe that

is not supplied in your apartment - somewhere. Further, with regard to lightning, you are probably already living inside a faraday shield (the building's steel, skeletal structure), but make sure you ground the coax coming into the apartment at the window or where it penetrates a wall. To answer my earlier question, connect the coax shield to the building frame before it begins its descent to your apartment.

>> Anticipating what follows, perhaps you should simply loop couple all
>> of that steel at the top of the building. No ground issue there. No
>> direct connections. No HV problems.
>
>Please elaborate. Do you mean turning the warship atop my bldg into a
>ground reference loop?

Think of a Gamma or Delta match. Although these connect to the metal of the structure they drive, they are inductive loops. You could as easily build the loop and place it in close proximity to the structure to accomplish the same thing. This gives you isolation except for the frequency the loop is tuned to (and would limit you to a narrow band of operation unless you have some means to remotely tune it).

>... for RF purposes, most of the
>sink effect comes from strapping together everything in sight,
>including cabinets, metal furniture, building structures, drains,
>floor support etc etc.

Suffice it to say it is adequate.

>I would like to maximize the chance that any burst of energy will take
>the ground path rather than the coax path. Why should putting, say,
>3kV insulation between the antenna and the coax not matter?

It is based on hope.

>Incidentally, you do find kV-range insulation in commercial products
>as well.

Much of that is simply opportunistic and chance given the insulation is suited to other purposes, like holding things together as a framework made out of plastic.

>> Lead dressing is adequate and mounting
>> does the rest.
>
>What do you mean?

Keeping leads apart and away from conductive structures replaces all the exotic insulation you could imagine. Besides, if we are talking about your T2FD and coax, I cannot imagine this is a problem in the first place. You are going to want to drive the coax shield to ground as soon as possible, not isolate it with insulation. You are going to want to isolate the T2FD ends, but any induced potentials will have to

reckon with the built in resistor snubbing them. Such potential does not merit heroic insulation efforts.

>So it snubs any EMP but not an RF signal. What is the spectrum of an >EMP? Is it more like DC or more like all across the RF spectrum?

It is mostly Pulsed DC with very little RF over 1MHz. The pulse shape is characteristically described as several ï¿½S rise and about 20 ï¿½S fall. If you consider the strike contains 100,000A and integrate this pulse over one second, then the duty cycle reduces this to 10 - 100 A.

This is not trivial, but neither is it catastrophic UNLESS that same current is trying to push its way through Z or R! Remember, lightning's source is an infinite constant current generator capable of supporting any potential necessary to maintain that strike level.

Consider this: You have a huge resistor of 1000 Ohms. You are within reach of one of its leads tied to ground. It is supporting 100,000A through it - hence there is 100 Million volts across it. You reach out and grab that lead going to ground. Are you going to be hit with that same gazillion volts? The ground lead presents all of 0.001 Ohm and with that same current, for 10's of ï¿½S you feel the tingle of 100V - Maybe. Your body resistance is easily 1-10 KOhms and the current of that 100V is enough to kill you if sustained (10's of ï¿½S hardly qualifies) but probably a burning pin-prick sensation. If we convert this burn into power, it renders you sinking (or simmering) 100 mW-seconds. In equivalent heat experience, this is like grabbing a Christmas tree bulb (the big ones) for a hundredth of a second.

>Now I understand. FYI, what gets you in a lightning near-hit _is_ an >EMP.
>
>I once had an audible arc in an antenna due to a 1-lightning >thunderstorm. That single hit happened in the midst of a city, and >took out several power stations and countless other equipment. My >antenna was 8 miles away.

You heard the arc. That is an expression of power. This power conversion is easily measured in the microwatts. It may sound loud, but hearing is deceptive because it is subjective.

Still and all, microwatts for the front end of a receiver can be overpowering. You can rest assured that this power was generated due to the current encountering either Z or R such that it was absorbed by the heat conversion.

>Great! But what about losses?
>
>I NEVER saw baluns with windings atop each other
>- they were always directly wound on the core.
>And I don't know why.

To maintain a wide bandwidth and to preserve balance.

>All of yesteryear's professional toob radios and
>many consumer ones included a tiny neon lamp in their front end.

I have repaired many such sets, professional and consumer alike. Yes, some included the NE-2. That practice was discarded just as many years ago too. There are probably a billion TVs out there, and not one of them with this kind of protection.

Returning to the issue of lightning, I would suggest you mine the archives of rec.radio.amateur.antenna for Richard Harrison, KB5WZI for thousands of commercial and amateur tower installations over a career spanning 50 years. He also discusses feedlines and lightning.

Cross-posted to: rec.radio,rec.radio.amateur,rec.radio.amateur.antenna

Thank-you so much for the feedback and information thus far.

Although I really appreciated the information, I do not want to get too hung up on the coiling of the coax. This weekend I plan to upgrade the gauge of the wire from #8 to #3. Also I have now bonded the cold water pipe entering in the basement floor to the exterior ground plate.

Any other feedback on the pictures below are appreciated......

Lloyd

- 3 ground rods 10' each around the tower (bonded together)
- 2 ground plates (one outside, one in the shack, also bonded together)
- lightning arrestors and/or feedthrough adapters
- tower to mast ground
- interior coax switch (not shown)

I provided some pictures below:

1724. VSWR Question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-13 17:19:43 UTC
From: Mike Coslo <mjc5remove@psu.edu>
Message-ID: <411CF82F.4000402@psu.edu>
Source record: 91045

Possible Dummy alert here!

I'm trying to understand VSWR a bit more here. As I recently put up my first non-ladder line antenna, VSWR has suddenly become important to me. 8^)

This isn't so much about the antenna, which is performing okay so far, if a little high on 80 meters.

More it is about a tuner's habit of showing a higher VSWR as the power level is increased.

I have read that this is not the case. VSWR does not change with power level, and that something is wrong with the VSWR meter, but what would be wrong with the meter, and more importantly, *which* is correct, my low power or high power, and how do I find out?

My Rig VSWR meter and my tuner meter read fairly close at the low end, but diverge at the high end. But both read higher VSWR than at low power. so that isn't a help.

I do have another VSWR meter, but at this point I suspect that adding another variable will just further confuse me! 8^P

Anyone have an explanation?

- Mike KB3EIA -

Hi Mike,

Meters display an error as a percentage of the full scale. This means
that 10% of 100W full scale is a 10W margin ANYWHERE on the scale.
Needless to say that if you are down at the 10W end of the scale, the
actual error is ï¿½100%. If you are up at the 100W end of the scale, it
is ï¿½10%. Hence there is the possibility that the SWR is the same, but
the error introduced at the low reading does not track with the high
reading.

Moral: Always adjust instruments to indicate full scale readings.

Simple. This has been discussed many times. The diodes are nonlinear and when on the low end of the voltage across them, they conduct differant.

To get the best indication of swr use the larger ammount of power. You can use the lowest ammount of power to adjust the tuner for the lowest indicated SWR . That will not matter. It is just the most accurate swr will be seen by the meter at a higher power level.

If you use a directional wattmeter that has a wattage scale and calculate the swr , it should be the same at all power levels provided the meter is accurate.

I think it is a simple case of the meter being somewhat less accurate at the
low power levels and different meters having different levels of accuracy.
I've used a number of meters and all have given a different reading at 10
watts than 100 watts. So I tune at low power and then give it a quick touch
up adjustment at the power I intend to operate.

The SWR meter's diode(s) forward voltage drop(s) has(have) to be
overcome before the SWR meter reading is accurate. Also, high
power may cause impedance changes due to heating.

Mike Coslo wrote:
"More it is about a tuner`s habit of showing a higher VSWR as the power level is increased."

Standing wave ratio (SWR) is often called "voltage standing wave ratio to distinguish it from the standing-wave ratio expressed as a power ratio which is (Emax / Emin)squared' (From Terman`s 1955 edition footnote on page 97).

SWR is a measure of the amplitude ratio of the reflected to incident waves at the load. It`s a means of expressing the reflection coefficient.

SWR is independent of power level or of transmission line length on an ideal line. Just as a speedometer doesn`t require driving a mile or for an hour for a valid mph reading, an SWR meter doesn`t require any particular line length to present a valid mismatch reading at the transmission line load, despite reasonable objections by Reg Edwards. The degree of mismatch can be indicated by an SWR meter in the usual case.

Power level is not an SWR factor but often plays a role in the indication of SWR as well reported by Mike Coslo and his respondents.

Good point! It`s akin to: "You can`t protect against a direct hit!"

Oh yeah? How about 10,000 medium-wave broadcast stations struck by nearly every charged cloud passing overhead? Sometimes several times a minute for a long time period. The listener is often unaware of the instantaneous carrier drops to extinguish the arcs initiated by the lightning strikes. And, one of the most important lightning opponents is a large coil of large wire in each tower lighting wire at the base of the tower. It keeps lightning as well as R-F out of the electrical service to the station.

If tower lighting chokes stepped up the lightning, they would all be replaced with Austin transformers or some other technique such as shunt feed of the radio towers to eliminate the base insulator. Truth is, lighting chokes are very effective at keeping lightning out of the power supply.

Message-ID: <EfbTc.7425$54.112703@typhoon.sonic.net>
Source record: 91057

I live approx 80 miles from the xmitter of station WABC (New York) 50,000 watts. During the day my reception is good-to-very good. After sunset however, the signal is poor to unlistenable -- due to fading and man-made QRM. The stations night-time signal is directional but I live in the direction of the major lobe. The station advertises covering 27 eastern US states at night -- which I don't doubt.

I can receive a Boston station (WBZ, 50k watts) and a Charlotte, NC station (WBT, 50k watts)at night loud and clear. Both of these hundreds of miles from me. (Also get WJR in Detroit and WLS in Chicago loud & clear.)

I seem to be in a "shadow" for the relatively close WABC. I'm using a high quality (Sangean) table radio with a built-in ferrite loop antenn. Any suggestions for improving my WABC night time reception??

Richard I've been amusing myself by trying to develop an antenna that "receives" RHCP polar orbiting satellites. The coverage I trying to obtain would suffer from the stacking refered to in this thread.
And, it seems so obvious that feeding the two antennas in phase would produce maximum gain on the horizon, that I thought there was some special requirement for this antenna's pattern.
In addition, I have assumed that the impedance mismatch for receiving antennas can be allowed to be much greater than for transmitting. This statement is directed to the fact that transmission line loss is increased by VSWR, and the reciever isnt restricted to being the same impedance of the transmission line.

Jerry

It's not a monster under the bed. But it is a heaven of a blast!

The actual USAF specification for lightning strikes is based on a
probability model.

It's been 20 years since I read the actual wording, but the values are;

90% of all lightning strikes in the USA are described as falling within
the spectrum defined by a strike with the following characteristics:

1) Double strike. First peak 100,000 amperes with a second strike of
50,000 amperes. Full Width Half Maximum [approximately 50% pulsewidth]
of 100 useconds for each peak.

2) Rise time from 0 to peak is 1 usecond on both strikes.

3) Fall time is a decaying exponential from peak to approximately 500
amperes sustaining current in the lightning channel for 300 milliseconds.

4) Electric field intensity prior to prestrike is greater than 10,000
volts per meter.

Conclusion: Lightning has lots of energy. Systems have been designed to
not only survive a direct strike but to operate through the direct
strike. All it takes is $$$$$$.

Note: 50% of all strikes use the same pulse width model but with a
reduced amplitude of 20,000 and 10,000 amperes for the peak values.

Art,

Without the radio signal from the transmitter, the receiver will
respond to noise and move the control servos to unpredictable
positions, pretty much always resulting in a crash. Modern PCM
receivers can be programmed to assume pre-set control positions in the
absence of the control signal. This will usually result in a crash.
I have hundreds of hours flying RC model aircraft.

Jerry, just because you are wanting to recieve, instead of transmit, doesn't mean that the V.S.W.R. mismatch isn't there-- nor its effect on the subsequent coax loss's being multiplied because of the mismatch! Remember- the antenna , coax, and the mismatch are all bi-directional ! The additional loss in the feedline, because of a high swr, is also present in the recieve direction! If you have copy of ARRL handbook, or other sources, look under "transmission lines" - these have a chart of coax loss, and also the swr effect on that coax loss.
For example, coax with 4 dB loss, at swr of 1.5 /1 would raise the line loss by an extra .1 dB, while an swr of 3:1 would rais it by an extra dB, at 5:1, would add about 2.2dB loss! and- keep in mind this is BI-DIRECTIONAL loss ! Another consideration is that the noise figure is optimized for 50 ohm, and this (because of a mismatch), will also be negatively affected! Best to find good impedence match for all considerations-- Jim NN7K

Hi Mike,

One possibilty for the higher readings is that the antenna is actually changing impedance at higher power levels. This happens when a loose connection changes resistance under higher current conditions, when vegatation contacts the antenna and changes condutivity under higher current conditions, and when corona or arcing occurs at higher voltage conditions but not at lower voltage conditions.

All of these conditions will usually indicate on the VSWR meter as a sudden jump in VSWR.

Hi Richard, really glad to see you chime in. Even ignoring the few examples I found that argue against the choke concept, what was more relevant to me was that in poring over hundreds of documents lately, I can find no modern specification for coiling the coax at any point, high or low. Not in the NEC or NFPA, not in the descriptions and specs to nationwide antenna tower systems, and not in National Lightning Safety Institute, University of Florida or other acedemia writings of such protection systems. So what seems to remain, is its record of use, perhaps prominently at one time, without evidence that the design was ever effective. Remember that for 230 years science seemed to support the pointed lightning rod without really testing it against other attachment points. Now it is fairly well agreed that blunt-tip rods were sceintifically tested to do a much better job of attracting the leader that was headed for a given area anyway. Perhaps the colied coax chokes are just fading away due to no real evidence that they work, and some theory and maybe even feeble arguments that they could do harm. From an EMI standpoint, it's hard to argue the concerns. And from direct attachment, only a massive winding of very heavy conductor could slow down lightning (providing there was an arc-gap for it to take as an

alternate to that slowdown). Might be why the modern lighter cabling of todays proliferant towers find little usefulness for the concept - just as a possibility.

Best regards,

Jack Painter

Off the wall question: What's the "butt-kickinest" high end radio these
days? PCM's been around for many years, anyone doing error correction, FEC,
Direct sequence spread spectrum?

Jim

I sure wouldnt argue with your findings. I guess this identifies my
sloppy engineering. I didnt think 4 Db was a tolerable feed line loss
under any but the most dire circumstances. I wonder what a ~3:1 VSWR would
do to add attenuation to feed line loss os, say 1 1/2 db.
To further identify my sloppyness, I cant distinguish zero db from 0.1 db.
It is even difficult for me to determine with any confidance the difference
between Zero db and 1 db.

What I'm getting at is -- I still contend that a receiver can tolerate some mismatches that arent tolerable in a sophisticated transmitting station. Richard Fry has pointed out how critical small mismatches are in FM transmitters. This original post referanced a FM transmitting antenna. It would be reasonable (to me) to assume this referanced antenna could have some rigid constraints if it was to be used for transmitting stereo FM. But, as a omniazimuth FM receiver antenna, the phasing might be fairly straightforward.

Jerry

Also, remember that diodes in your swr meter are NOT LINEAR, until the
voltage
across them reachs a certain "Point" (below that point, they respond
as a square law device - double the volts, QUADRUPLE the CURRENT! The
diodes are on the sampleing lines of your vswr meter, and measure
forward (current)!, and backwards current! It is as simple as: double
the power- quadruple the current flowing in the sampleing circuit! This
is a common problem with a diode at a lower power than it is designed to
handle-Jim NN7K

That's not quite correct.

The SWR on the line is determined solely by the transmission line impedance and the load impedance. When transmitting, the antenna is the load. When receiving, the receiver is the load. If the receiver and antenna have different impedances, the line SWR will be different when transmitting than when receiving.

Fiddling with the antenna or the antenna/feedline match won't have any effect at all on the line SWR. It will, however, have an effect on the strength of signal arriving at the receiver.

Jerry-- at your stated 1.5 dB loss coax, with a 3/1 vswr, the extra loss would be just under .7dB, but remember that the reflected mismatch, also will affect your recievers front end noise (factot/figure), most likely in a negative way (no way to calculate the impedence presented to your rcvr front end) also, remember that fm sensitivity (because of its nature) is not near as sensitive as cw/ssb (typical 2 meter rcvr can detect a signal below .01 microvolt cw - fm rcvr does good around .1 microvolt- 20 dB more sensitive! Something to think about-- jim NN7K

What difference does the motive power have with regard to the control system? A gassie will react the same way as an electric does when they lose the transmitted control signal, whether by failure or by going out of range. An AM or FM radio will react unpredictably when confronted with loss of signal. PCM radios are more immune to interference and can be pre-set for failure. Or, are you saying that the method of powering the model makes a difference in what happens during radio failure? Even if the model is dynamically stable (most are), if the servos apply full pitch up and full rudder, a spin will ensue. I have built and flown almost every kind of model aircraft, rubber, gas and electric using every kind of contol system including none over the last fifty years. A "back-yard" electric from the bargain store will crash without control. The model can be built light enough so that little, if any, damage will be done. Of course, there is always the chance that the controls will fail in such a position that a glide to landing will occur. In that case, go right out and buy a lotto ticket. Some of those "no control" models used a method using a fuse to burn a rubber band that allowed the empennage to pitch up. The model would stall and (hopefully) return to earth in a steep, deep stall. Little or no damage was sustained because of the lightness of the construction.

Hi Dave,

I've been away from it for a couple of years, moving, work and
other expensive hobbies. The high-end Airtronics, JRs and Futabas are
still the top of the line. They use PCM but no ECC, FEC or SS. The
transmitters are pretty programmable though. No need for a seperate
heli radio, just program the mixing for a heli control system. The
computer allows for memories for different models, each with custom
mixing and end-point adjustment. No more sliding servo trays for
elevon deltas. Just put a servo on each control surface and mix
appropriately. Dual servo ailerons or flaperons, no problem - just
set 'em up in the TX. You can spend a grand easy on a radio these
days.

Funny, I just got a bunch of stuff out of storage last week
(new house - YAY!) and was looking at a couple of planes longingly.

Not these stations. They are so-called "clear channel" stations.

Hi Art,

Historically, three letter calls in the AM band were designated as
"clear channel" stations and are generally always lit up at full
power. "Clear channel" was meant to serve a vast region out of major
metropolitan centers. KVI is one here in Seattle, KGO in San
Francisco, WGN & WLS in Chicago, KOA in Denver, KFI & KNX in Los
Angeles, WSM in Nashville, WWL in New Orleans, WBZ in Boston, WHO in
Des Moines, KYW in Philadelphia (strange listing) and so on. Almost
across the board all transmit 24/7 at 50KW with omnidirectional
antennas. Not all three letter calls are clear channel, what with the
change of time and market and financial backing.

This would account for the strange undulating "out of phase" sound -- with the ground and sky waves canceling and reinforcing in a random manner.

Seems to me that there is not much use having 50k watts if the signal in the station's market area is virtually unlistenable. Then again, most of the commercials at night are "national", not "local".

Hmmmmm.... haven't tried that. The use of a non-directional "whip" (car)
antenna might actually help to seriously attenuate the ground wave yet
"grab" the sky wave.

AM BCB DXing in a car/truck at night is a popular hobby I understand.

1758. AM BCB Long Wire

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-14 07:26:41 UTC
From: Dave Pitzer <dpitzer@sonic.net>
Message-ID: <R8jTc.7502$54.113585@typhoon.sonic.net>
Source record: 90979

Would 16 ~ 18 gauge lamp cord (Zip cord) make a good "conductor" for an AM band external long wire? Pull it "apart" and splice for maximum length? or just use one "side"? or "short" it at the far end or at both ends? String it at about roof height? Beyond, say, 100 feet, how important is length?

Thanks in advance.

Dave Pitzer

Oops. I meant, WHEN RECEIVING, fiddling with the antenna or the antenna/feedline match won't have any effect at all on the line SWR. It will, of course, change the line SWR when transmitting.

Make it as long as possible. Split the wire and solder it end to end. Depending on your receiver, a simple LC tuner will help cut down on images across the band due to receiver overload (unless you have a R75 or such). Roof height is plenty high enough.

Good luck !

Various types of "anti-fade" radiators are used by many of the 50kW stations to try to minimize this effect.

There is a tradeoff in the electrical height of the usual AM broadcast transmit antenna between producing the greatest groundwave and generating an excessive high angle skywave that can interfere with that groundwave at night.

A 225 degree vertical is about optimum for groundwave, but has a high angle lobe that can cause this type of interference problem. A 195 degree vertical has less groundwave but little/no high angle lobe, and so is used by many full time 50kW stations. WJR, Detroit is an example of a station using a 195 degree vertical (700 foot guyed tower).

Other antenna types also have been used for this, such as the "Franklin," which is a sectionalized antenna with one vertical radiator above another, each driven separately.

Note also that the carrier frequency of the station, the conductivity along the groundwave path, and skywave propagation conditions will have an affect on the location of this zone, and the extent of interference there.

R. Fry

The following QST from ARRL makes me sad. I recall working Bill, W9INN, on CW in the early days with my WT7AAN call and was thrilled to say I was using a W9INN 40/80 dipole. His antenna is still in use at my QTH with additional legs added for other bands. Bill was an asset to our hobby and will be missed. I learned a lot about antennas from his detailed instructions provided with each antenna and will always remember the smallest ad in QST from W9INN.

You may find that stuff to be too "stretchy". I.e., after you get up
up and taut, several days later you may find an unacceptable sag in it.
You'll pull it tight -- and again, it'll sag.
Eventually you'll have a _much_ longer antenna made out of 22 ga. :-)

At least, I think that'll be the situation with the length(s) you seek.

Lamp (zip) cord is manufactured for 'flexibilty' -- not tensile strength.

Directivity is more important on the AM BCB band. Consider making
a tunable loop (one foot diameter or so..) that will allow you to peak
the direction for desired stations.

Hi Dave,

The point of the monster is that it is NOT under the bed, but in the
heavens. Let's look at the numbers you provide:

>First peak 100,000 amperes with a second strike of
>50,000 amperes. Full Width Half Maximum [approximately 50% pulsewidth]
>of 100 useconds for each peak.

Expressed as power into a section of tower where the cumulative
resistance is 1 mOhm (not unreasonable) and giving the stroke a full
second sustained current flow (I've never seen such a long one) so we
can round the numbers into watt-seconds (never mind KWH); and figuring
a duty cycle of 0.01% based on your pulse width, but let's get
extravagant and say 0.1%; then both strikes express all of 150
milli-watt-seconds of power.

>500 amperes sustaining current in the lightning channel for 300 milliseconds.

Again, expressed in watt-seconds (sneering KWH) this probably doubles
the power burden another 150 milli-watt-seconds. Total power: less
than half a watt-second or as much heat as 1/10th of a Christmas tree
bulb held for the same time as the strike. For those who remember
NE-2 bulbs in their radio's front end, these are rated at 1/4 Watt.
The paranoid may wish to parallel several, but such devices exhibit
what is called current hogging - one will fire to destruction before
the others light up.

To demonstrate the catastrophe that is so often associated with a
strike, divert the same strokes to a nearby tree that shows all of 10
Ohms resistance in its sap: 3 KW-Seconds. Try holding three clothes
irons for 1 second. :-)

Even this is barely remarkable given the heat is spread over a
considerable bulk. What makes the difference so destructive? That
same time element. The heat does not have the leisure of dissipation
in 100ï¿½S and concentrates. This accounts for the scoring of a strike

on metal, or the steam explosion in a tree trunk.

>4) Electric field intensity prior to prestrike is greater than 10,000
>volts per meter.
>
>Conclusion: Lightning has lots of energy.

Energy is a strange thing, sunlight has vastly more energy than radio waves at HF (or VHF or UHF or SHF or....) No one worries about their radio at the beach, but they put sun screen on their skin. Walking across a wool carpet generates far more energy than a pre strike, but hardly enough power for a pinwheel. Separating two sheets of typing paper is about the same risk.

This does not diminish the liability to sensitive components. The electric fields created by the casual separation of paper can destroy a transistor IFF it is not in a circuit. The power absorbed by common, resistive components in relation to that same transistor protect it simply. There are some circuit designs that seek a high input resistance that easily fail to this assault. I should note that in this day and age of surface mount that there are also resistors that can be destroyed by these casually generated potentials.

>Systems have been designed to
>not only survive a direct strike but to operate through the direct
>strike. All it takes is $$$$$$.

Well, for the amateur (not working through a strike) perhaps $$.

The risk is: "Do you maintain 0.001 Ohm or better strike paths?"

Thin copper wire does not keep stretching for ever. In general it only stretches once under a given tension.

Copper has the very useful property of work-hardening as it stretches. If the tension is not increased further than its previous maximum tension it remains at the same length.

If any part of a length has a tendency to stretch more than another, perhaps because it is slightly thinner, then that part hardens first until the remainder catches up.

Give the wire a good stretch, to make it dead sraight, before erecting an antenna and it will remain at that length. Electrical properties will not be significantly affected.

I have used the same thin 18 and 20 gauge, enamelled, magnet, antenna wire for many years without any problems of this sort.

For All,

reference "The Electromagnetic Bomb (E-Bomb)":
http://www.airpower.maxwell.af.mil/airchronicles/kopp/apjemp.html

"The ElectroMagnetic Pulse (EMP) effect [1] was first observed
during the early testing of high altitude airburst nuclear weapons
[GLASSTONE64]. The effect is characterised by the production of a
very short (hundreds of nanoseconds) but intense electromagnetic
pulse, which propagates away from its source with ever diminishing
intensity, governed by the theory of electromagnetism.
...
"Even if the pulse is not powerful enough to produce thermal
damage, the power supply in the equipment will readily supply
enough energy to complete the destructive process. Wounded devices
may still function, but their reliability will be seriously
impaired. Shielding electronics by equipment chassis provides only
limited protection, as any cables running in and out of the
equipment will behave very much like antennae, in effect guiding
the high voltage transients into the equipment."

Note, the EMP of the Flux Compression Generator, an example of a
tactical E-Bomb, is VASTLY richer in current unlike a lightning
strike:
"The FCG is a device capable of producing electrical energies of
tens of MegaJoules in tens to hundreds of microseconds of time, in
a relatively compact package. With peak power levels of the order
of TeraWatts to tens of TeraWatts, FCGs may be used directly, or
as one shot pulse power supplies for microwave tubes. To place
this in perspective, the current produced by a large FCG is
between ten to a thousand times greater than that produced by a

typical lightning stroke [WHITE78]."

However, these intense currents are not widely suitable for mission purposes for the same reasons of the Lightning's current pulse: "Whilst FCGs are potent technology base for the generation of large electrical power pulses, the output of the FCG is by its basic physics constrained to the frequency band below 1 MHz. Many target sets will be difficult to attack even with very high power levels at such frequencies..."

Details abound in this paper, which I will leave to the student to absorb. Of particular note are the statements about coupling efficiency (unpredictable) and range (hundreds of meters).

1777. Vertical dipole, helically wound - comments?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-14 19:19:46 UTC
From: Thomas <nospam@nospam.com>
Message-ID: <10hspeh1srk3931@corp.supernews.com>
Source record: 90998

I have taken two lengths of 1.66" OD (1-1/4" nominally labeled) PVC pipe ("top" is 5 feet long, "bottom" is 10 feet long) and connected them with a PVC "T" joint.

On the top I have wound 210" long 12 gauge, solid copper wire to cover about 4.75 feet of the "top" PVC length and done the same on the "bottom".

I feed a length of RG-8 into the bottom of the pipe and out the "T" joint and connect the center conductor to the top winding and the braid to the bottom winding.

The whole smash is then mounted vertically in an old umbrella stand.

So I have a vertical dipole with roughly lambda / 4 (for 20m) length of radiator top and bottom. I was not sure whether to wind the top and bottom the same way so I "matched" them insofar as they look like the continuous threads of a screw. Not sure if that is right.

Seems to work well as a receiving antenna, not sure on the transmitting part as yet.

Comments, especially regarding construction changes and tuning would be welcome.

Thanks.

Hi Richard - can you please explain this "duty cycle of 0.1%" ? I thought it was expressed as a 10% duty cycle - but then a 50kva strike would be expressed as 5kva sustaining current in the lightning channel, not 500 amperes. Dave - was that 500 amperes a typo or the figure used by the USAF for protection design? My internal surge protection is designed for 10kva max, and the rooftop downconductors would certainly be expected to carry at least 5x that much for a short time from a direct attachment. Even internal AC wiring is designed to carry 6kv/1kva before dialectric breakdown. Which does incidentally happen from those 100kva strikes. It just happened less

than half a mile up the beach from me last month.

Thanks,

I see 2 problems here Thomas. You are confusing the length of the wire you wound into inductors as having the same electrical length as a straight piece- nothing could be further from correct. In fact, the relationship between the amount of wire in the coils and their equivalent electrical length is complex and depends on a number of factors including where along the radiator the inductors are placed.
Secondly, running the coax up inside the PVC will likely result in a large amount of RF being impressed on the exterior of the coaxial shield.
Visit Reg Edward's site to see how to electrically shorten a radiator with inductive loading.

wrote:

>Hi Richard - can you please explain this "duty cycle of 0.1%" ?

Hi Jack,

Duty cycle is a simple ratio of on time to off time. It would be
presumptuous to offer that the strike off time for any particular spot
on earth is hundreds of years, so the choice of one second is suitably
long enough given strike components have long since faded, but are
easily recent both.

The shape of the pulse complicates the estimate because Duty Cycle is
often expressed in the expectation of a square wave. What is the on
time? When you get into pulse work, most in the field arbitrarily
assign the width of the half-power, or half-voltage points. For
Dave's numbers, this would be some 100ï¿½S which, when compared to 1
second is actually 0.01%. Being generous, and given the shape of the
decay I simply threw in a 10X fudge factor.

> I thought it was expressed as a 10% duty cycle

10% of what? Lightning current flows for 100ï¿½S and is off for 1mS?
Dave clearly expresses lingering current flow out to 300mS so that is
clearly wrong.

> - but then a 50kva strike would be
>expressed as 5kva sustaining current in the lightning channel, not 500
>amperes.

Where did the volts come from? If the pre strike fields are running
10KV then your strike has only 5A in it. This is the pencil whipping
that comes with lightning: the voltage description. ALL of that
voltage is dropped across 10000 feet of discharge length, not in the
last 3 inches from the tip of the bolt to ground.

In normal, settled air, in the most benign weather without any
disturbance, the potential gradient from earth to sky is 180V/M. That
is to say, your head is at an elevated potential of 300V with respect
to your feet. At an altitude of 10000 feet the potential is
1,800,000V without any inducement to discharge.

You need to look at those surge protection ratings again. My
experience is that they are rated in Joules capacity which is NOT the
same thing as v-amperes. The two may be equivalent, but your
reference for volts is missing altogether. As I offered in other
postings: where did the voltage come from? If your tower is of the
standard design, you are not going to develop any appreciable voltage
unless you introduce resistance or impedance to develop it from the
current flow. 100,000A through 0.001 Ohms may give you 100V at best,
and only if you can reach the top of tower where the strike hits.

For those who want to multiply this voltage with Z, calculate the
impedance of a 12" diameter wire 50' tall at a frequency of 1MHz.
Perhaps this will make an NE-2 glow, if its leads are long enough.

> It just happened less
>than half a mile up the beach from me last month.

No doubt, but what exactly was "It" that happened? Stick 50 feet of
tower up into the air, and interrupt it with insulation and YES! arcs
will spark. No one needs an insulated $$$$$$ tower - thousands of
commercial installations typically discard that feature in favor of
simple $$ lightning protection.

Richard,

Thank you for the exhaustive reply!

> [...] this works for RF but for lightning that
> is another matter (and at different frequencies simultaneously).

LOL!

> Your need for ground when you are using a dipole is unwarranted in
> terms of RF.

Yes and no. A "stand alone" antenna such as a dipole is not worked against a RF ground. (BTW, I remember seeing Hertz's original dipole in a museum in Wuerzburg... & I swear it wasn't grounded). But a ground is a good pulse sink if it is very permeable across the spectrum. In that sense, a pulse sink should be a decent RF ground too.

> Make sure the ends stand off
> from the supports by a good amount - I can only guess, and that would
> be 10 feet.

Absolutely!

> Insofar as safety ground goes, it is hard to believe that

> the coax coming into the apartment at the window or where it
> penetrates a wall. To answer my earlier question, connect the coax
> shield to the building frame before it begins its descent to your
> apartment.

I wish...

In this part of the world steel structures are unheard of 'cept in industrial buildings. The tallest building in the country is only 30 floors, and its structure is reinforced concrete. Also, walls are always some form of brick & mortar ot at least gypsum. This explain why fire safety & property insurance are almost an afterthought here. We do have disasters, but very few in post 1930's high rises - mostly it's cheap built 19th century buildings collapsing after a gas explosion. Otherwise, one flat may burn out but others won't be damaged.

Also, a power grounding is very effective for low frequency events. If you get zapped by a pulse, all bets are off if your ground is high

impedance - and an end-fed thin ground wire is. In my case, the
shortest route to the building ground connection on my floor is almost
100 ft with lots of zigzagging.

> of operation unless you have some means to remotely tune it).

I had never thought of that. So a broadband / omni antenna puts a bit
more punch into the coax than a narrowband / mispointed beam. But I'd
still rather put up a simple, forgiving, uncritical broadband, even if
known inferior.

> Keeping leads apart and away from conductive structures replaces all

> reckon with the built in resistor snubbing them. Such potential does
> not merit heroic insulation efforts.

OK, I'm abandoning the heroic insulation efforts. I'll ground the
coax up on top, and introduce an insulating transformer to decouple
grounds only if double grounding introduces noise - that can be done
later at the shack end of the coax.

> >What is the spectrum of an EMP?

Now I know what to expect when I wile away a thunderstorm sucking an
antenna plug.

> >I NEVER saw baluns with windings atop each other>
> To maintain a wide bandwidth and to preserve balance.

Got it!

> I have repaired many such sets, professional and consumer alike. Yes,
> some included the NE-2. That practice was discarded just as many
> years ago too. There are probably a billion TVs out there, and not
> one of them with this kind of protection.

Things change. Just as many more people now enjoy the other side, most
TVs get their storm thrills through the power socket nowadays -
especially if served by cable :0. Open a PSU, and you'll likely find
MOV's. Not good for RF work because they tend to have too much

capacitance....

And TV antennas tent to be 1) tiny 2) narrow beam, 3) tuned to UHF. No protection againt a direct hit, but non that sensitive to near hits.

The market for gas discharge devices for many kinds of RF applications is still quite lively though, and it's not for protection against nearby transmitters.

> mine the archives of rec.radio.amateur.antenna
> for Richard Harrison, KB5WZI

I'm grabbing my steel hat as I type!

73, thanks again.

1782. "Miracle" DLM RI short vertical

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-14 23:02:01 UTC
From: k3bu@aol.comNoUsama
Message-ID: <20040814190201.10759.00001227@mb-m13.aol.com>
Source record: 91003

Howdy NGers,

I was curious about another "miracle" short vertical, being subject of great interest, patent by Robert Vincent and Physics dept. of University of Rhode Island. I got up at 4 am, drove to Boxboro ARRL convention and eager to see what are we missing.

Not much!

Giveaway was opening statement something like: how to make shortened antenna with more gain (compare to what? I guess light bulb :-)

In the "theoretical" portion of the presentation audience was told that current across the helical coil decreases away from the feed point, while across loading coil it stays constant. Due overcrowding of "inventor" I did not persist in breaking through and asking for enlightenment.

Author claims more gain (familiar), better bandwidth (doesn't get it why) and small size (of course). Showing measured graphs with current and phase distribution along the radiator. Works very well! (Many stations worked.)

He showed how to measure current at the antenna using ferrite pickup transformer way up the antenna and cables to the instrument (handsomely detuning and distorting the measurements).

I suspect that "broad bandwidth", (SWR 2:1) was achieved thanks to losses in the coils and dielectric, as "confirmed" by his statement that coils were fried when power was applied.

What is it? Basically helically wound coil starting from the base, about half way up the radiator, then piece of straight tubing, than loading coil, then tubing and in some case top hat (works better :-). Matching to 50 ohms is done by picking tap at the base, few coil turns up. That is 3D version.

He showed some "2D" versions, having "coils" made of basically coil formed as hairpin loops instead of classic solenoid, also the loading coil. So kind of 2D - 3D antenna :-)

I wanted to make a bet that my single loading coil loaded vertical would cream the "miracle", but there were so many worshippers paying compliments to the inventor, that I resigned not to stay for the second hour of lecture how to build it.

I saw no trace of any modeling, just experiments using wrong tools.

So brace yourselves for another "miracle" in the arsenal of very small and more efficient antennas. It should be a hit with CBers and other suckered users.

So that's it (oh, no chokes in the feedlines), I hope U of RI is proud of this breakthrough, I can sleep well now. Back to DR1.

Yuri, K3BU
with more info that could have saved lotsa experimenting at

I once fixed a TV that suffered a direct hit. The tuner in the corner of the cabinet was enveloped in a charred, molten mass of plastic but still worked fine.

This was back in the tube days however, and they were far more robust against EMP.

>

Richard,

Thanks for the response and the "inside", technical information about Broadcast-band-AM stations. I'm happy to say that here in eastern Pennsylvania, WJR has a beautiful night-time signal. About the only thing that disturbs it is "local" weather-based QRM --- i.e. Mother Nature!!!. I even recall listening to WJR in my college days in Charleston, SC in the early 1960's (along with WLS in Chicage and WOR in NYC).

Without knowing, I would guess that WABC (770 KHz) has a rather high angle skywave since its ground- and skywave seem in a constant "tug-of-war" at night --- at least ~80 miles to the northwest of the xmitter.

Thanks,

Dave Pitzer

I think the main problem you'll have is feeding the coax through PVC -
you'll likely get lots of rf onto the braid.
think about feeding through some metal pipe - to protect the coax from
induced rf

Does anyone know of a "good" listing/directory of either U.S. or North American AM broacst band stations ---- with cross listings by call-sign, frequency, location and possibly radiated power?

In other words, a broadcast band DXer's "bible". There surely must be one --- or is BCB DXing not the hobby it once was?

Thanks,

Dave Pitzer

Not sure, but it is apparently very easy to scale up or down by simply reducing/enlarging it on the copier by factor x. No kidding! Apparently works well into the UHF bands :-) Who needs EZnec.

Can you picture all them wizards joining forces for FracEHDLMCFA gizmo?

Only the those destructive MOV power strips get rated in joules ;-)

My normal-mode silicon diode surge suppression is rated in KA (not kva,
sorry again).

http://www.transtector.com/documents/salessheets/1451-001.pdf

the 10ka model has a 12,000 amp surge rating. I located one at the main AC
entrance panel (load side) and one on the station's 240v branch panel.
Transtector also produces "power strip" surge protection that is all silicon
with NO MOV's and NO L-G references. My station has no AC surge protection
references to ground, and all equipment is connected to L-N surge protection

power strips. Except the computer which runs through an Amer.Pwr.Con. UPS - which although it has an unavoidable L-G MOV, it is first protected by the two Transtector Fortresses.

A strike on a home and/or power lines in which the surge was so powerful that it blew the electric meter clean off the wall of the home (burning the powerline and the service panel inside the home). I visited when it was still smoking but they discouraged my camera. I did get a good picture of my neighbor's pine tree striped from 75' in the air to 6' above the ground, where it jumped to and split a wood fence. That was about 50' from the end of my 60 meter dipole which was operating at the time. I'm thinking the surge protection is working as advertised this summer. At this rate I'll soon have more examples that just nearby strikes......but hopefully not.

Hi Dale, yo took the words right out of mar mouf.

Program HELICAL deals with a vertical, continuously-loaded, plastic-pipe antenna, above a ground or above the roof of a vehicle. Because of the uncertain surroundings the program will put you in the right ball park with the number of turns on a pipe of given length and diameter. Putting two antennas back-to-back allows the design of short dipoles without any ground loss.

Program MIDLOAD deals directly with short, centre-fed, continuously-loaded 1/2-wave dipoles with a variety of feeding arrangements. May be either vertical or horizontal dipoles versus height above ground.

These antenna programs are most suitable for the 160, 80 meter and perhaps 40m bands where space is at a premium. At the higher frequencies lump-loading coils can be (or must be) used.

The advantage of continuous helical windings is that THICK, spaced, wire (copper pipe even) can be used. Thick wire means low loss resistance and higher radiating efficiency. Otherwise there's no point in using long helical windings.

There are a variety of my programs which use lumped loading coils some of which incorporate coil design and feedpoint impedance-matching arrangements. In the website refer to the one-line descriptions following each clickable program name.

Incidentally, changing the subject, the reason for using single-turn coils for magloops is that it allows a VERY thick conductor, a 1" or 2" copper pipe, to be used. Otherwise there's no point in using a magloop for transmitting purposes. The magloop is by far most efficient of all the small (in terms of wavelength) antennas. The disadvantage is its expensive or heavily-engineered tuning capacitor. Use program MAGLOOP4 for an accurate performance analysis.

For all readers, download the small, single-file, easy to use, programs in a few seconds from the following website and run immediately. Get your money back if dissatisfied!

Source record: 91016

... and, though it may not have importance at HF, any loss in the transmission line (unless it is very cold) will add noise at the same time that the signal is attenuated.
Once upon a time, serious consideration was given to using liquid air (might have been Nitrogen) to cool a rather short piece of waveguide (between feed and first receiver stage) in a really high frequency system that was pointing out into space. Such cooling would not have changed the attenuation a noticeable amount, but it would have improved the SNR.
... and further: please do not think of using the maximum-power-transfer theorem to maximize SNR. The first stage needs to see a (small) mismatch, which might not be seen by the transmission line.

With a low directivity antenna in the absence of close man-made noise sources, the above issues are usually of no importance at HF and below because the SNR is almost always (in a reasonably well designed system) determined beyond the antenna. [Obviously, a highly directive antenna system could dramatically affect SNR]

I've often wondered at exactly what crossover point a helical coil
turns into a loading coil. If one adds a one inch stinger to a helical
coil, does that turn it into a loading coil? How about a one foot stinger?
Is a one foot long loading coil not a helical coil? Does a one foot long
loading coil really have less phase shift than a one foot long piece of
wire? On a center-loaded mobile antenna, how can the ARCCOS of the current
at the feedpoint be zero degrees and the ARCCOS of the current at the tip
be 90 degrees without there being 90 degrees between the feedpoint and the
tip? (When are you going to invite everyone over to Bar-B-Q that sacred cow?)

As I understand it, he is feeding the coax through the center of
the bottom helical coil. What's going to protect the coil from
the metal pipe? :-)

Yuri, your criticism is perfectly sound.

To sum up, the key to antenna radiating efficiency is SIMPLICITY.

The more simple the construction of an antenna the more efficient it will be.

It is intuitivly obvious. Every complication is sure to introduce loss.

Unless they have added a lot in the last 3 or 4 years, WRTH's domestic MW listings are pathetic*. White's Radio Log is long gone, unfortunately, so Dave's best bet is to contact the "National Radio Club" which specializes in BCB DX (until BPL and digital take care of that). Run NRC through Google, Dave, they have a large web presence.

*example starting at the low end: WRTH lists 2 stations on 550 kHz. A very old (1975) pattern book from NRC lists 22 US stations.

Hi George,

84 pages of double column listings is pathetic? Compared to what?

I see 14 US stations listed for 550KHz not 2:
KENI
KQY
KUZZ
KRAI
WDUN
KFRM
KUSA
KBOW
WGR
KFYR
WKRC
KOAC
WJMW
KCRS

On a casual glance, the shortest listing for any AM frequency has 10
stations and the longest listing has 44 (and it is hard to tell if it
is the longest because there are so many of apparent equal length - in
at least 25 frequencies).

You are looking in the United States country listing for large
stations. The comprehensive coverage for all AM stations is found in
the back. Quite a difference!

Have a look at this:
http://www.waniewski.de/id35.htm

The text is in German, but the diagrams and photos show an aerial system
with its feed at 90 meters above ground level, to reduce skywave.
You can click through several pages at the top (1-15).

1814. Re: DLM Antenna talk

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-15 11:35:16 UTC
From: fractenna@aol.com
Message-ID: <20040815073516.11752.00003220@mb-m11.aol.com>
Source record: 90935

There were about 80 people at the talk, including a number of hams who are/were antenna professionals; academics; and so on. I was there for most of it; it was two hours and thus had the time frame for a substantial brief.

I saw and heard nothing that--in my opinion-- constitutes 'new' or 'revolutionary'. Although the statement "97% efficiency " was made for a shortened, DLM by Mr. Vincent, I saw no data that supported that claim. I did not see wide bandwidths in the data. The antennas are small. That claim is supported.

I did not see any evidence of improvement over the extant art of distributed loading. What I saw essentially confirms my earlier comments from June and July in this forum. Note: I was not aware of Mr. Vincent's design for the DLM until yesterday.

If I missed something, or make a statement here that is factually inaccurate regarding the statements of Mr. Vincent, apologies ahead of time; and please fill me in on this forum.

As promised earlier relative to the extant prior art: I draw reference to an existing, patent pending, commercial antenna by our friends at Astatic (the microphone company). It is sold by Omnitronics. It is called the "3K Antenna". The antenna is targeted for CB'ers and truckers, but it also works and is used, by hams on 10M. It , in appearance, looks identical to some of the DLM antennas Mr. Vincent presented. There is an inside cutaway which shows, in part , a vertically oriented helix (linear load); a "midsection"; a loading coil; and a top whip. I have one here. See:

http://www.astatic.com

Mr. Vincent confirmed that he was unaware of the Astatic antenna until I mentioned it to him yesterday.

I have offered to elaborate on a critique of Mr. Vincent's technology on the web, which I will produce, if needed. It may not be necessary for me to educate this way, as a number of people were/are capable of such assessments based on the info provided, and Mr. Vincent stated that he will post the PPT of the talk on the web. Doubtless there will be further independent discussion.

Just as a matter of protocol, in a public talk that has benefited from many years of guidance under an academic physics department, may I make the following brief (albeit not complete) suggestions:

1) Understand that a widely spaced helix has air cooling such that the cooling rate can substantially exceed the heating rate. Therefore the helix may dissipate heat and does not heat up much. That does not mean the system is lossless, nor that the efficiency through the helix is high.

2) Never claim that the efficiency of any electronic component as 100% ("lossless through the helix") just because the current profile stays relatively flat across it, and it doesn't burn up.

3) We have all used chicken wire(as ground screens), but may it strongly be discouraged. The losses are frequency dependent and often high;

4) Do not discount any ground counterpoise--especially one with 1/8 wave radials as being --in considering monopoles. It is an antenna system. This is part of the system;

5) Avoid PVC in monopole construction. At some frequencies the losses are reasonable, at others it is high. It varies from manufacturer; thickness; and so on.

6) Do not compare gains on a thin-wire type 1/4 wave monopole to a thick (diameter) helix-based antenna with a far larger electrical length, over a lossy, small counterpoise, and infer the efficiency.

7) Do not use wood in the near field when using MF/HF for probe measurements.

My brief thoughts at moment. More later if needed.

73,
Chip N1IR

h, but let's get
> extravagant and say 0.1%; then both strikes express all of 150
> milli-watt-seconds of power.

Richard, I'm not going to try to out calculate you.

But, please tell the group what the junction temperature of any semiconductor device is at transient thermal failure at 0.1 and 1.0 useconds.

Twenty years ago the USAF test data indicated that failure occurred at 0.5 microjoules!!! That's 300,000 times more sensitive than your numbers.

Note, it is extremely difficult to really achieve a 0.001 ohm mechanical interconnect.

Secondly, the major electronic failure mode is from the coupling of the magnetic field. A di/dt of 10^5/[1E-6] yields a value of 10^11 amperes/second. A one foot length of wire has a self inductance of approximately one nanohenry [1*10^[-9]] and the di/dt impact is ... 100 volts peak from one end of the wire to the next.

Back in the olden days, twenty years ago, the action integral, that you calculated was sufficient to burn a 0.5 inch diameter hole right through titanium that was 0.1 inch thick. Note: the titanium alloy we used melts at slightly below 2000 degree F.

The design issue is TRANSIENT THERMAL EFFECTS not average heating. At 1 microsecond the heat flow from the stressed area has not started. The USAF required adiabatic heating as the peak temperature for the starting condition for the transient thermal analysis. Restated, all the energy is converted to instantaneous heat and then the thermal stress analysis would be performed under that constraint.

Conclusion, lightning is a highly stressful environment.

However that doesn't mean that it's unimportant to match the feedpoint impedance of a rx antenna to the feedline connected there.

A rx antenna with a mismatched feedline will not deliver to the rx end of the feedline the maximum possible energy available from the fields in which that antenna is immersed. Whatever received power that is reflected by a mismatch at the rx antenna feedpoint is re-radiated (less losses).

RF

>that antenna is immersed. Whatever received power that is reflected by a
>mismatch at the rx antenna feedpoint is re-radiated (less losses).

What both Roy and Richard say is correct in principle, but may be missing the point about what a receiver needs.

What's usually important is to present the RX input with the *source* impedance it was designed for. (Most often this is 50 ohms, and let's also assume 50-ohm line for the rest of this discussion.)

Likewise the transmitter needs to be presented with a 50-ohm load impedance, so those two requirements coincide.

In order to achieve a 50-ohm load impedance for the transmitter, and a 50-ohm source impedance for the receiver, the antenna itself must be matched to 50 ohms - so that's your design aim.

Now when Richard says:
> Whatever received power that is reflected by a
>mismatch at the rx antenna feedpoint is re-radiated (less losses),

that is true in principle, but more important is that if any energy is reflected from the receiver input, that is perfectly OK - that energy was "not wanted" by the receiver. The receiver *does* want a 50-ohm source, but it only takes what it needs from that source. For example, a simple tuned-gate FET amplifier only needs a voltage swing at the input - it doesn't need current as well, so most of the incident power is reflected. That type of situation is very common in receiver design, and completely OK.

It is a myth that a receiver input is not optimized unless it presents a 50-ohm load. What it does need is a 50-ohm source impedance. The design details about input reflection coefficient are much more complex, but

the underlying principle is simply "The RX input takes whatever it needs from a 50-ohm source, and reflects the rest."

RX inputs *can* be designed to present a 50-ohm load impedance, even with FETs, but this requires special design techniques that generally involve feedback. It is usually done when some other device has to be inserted between the feedline and the RX input, eg a filter which requires a 50-ohm load impedance. But that device probably requires a 50-ohm source impedance too, so you still have the same requirement for the antenna to be matched to the feedline.

I'm putting up an offset dipole. I'm attaching a 4:1 balun. I'm running RG-8 to the balun. The dipole will be attached at 20' and the other end will be about 40'. My question is can the coax be tie-straped to the short end of the dipole antenna wire and run back with it toward the houes? This is basically to keep a big loop from hanging down and also keeping the wife happy since it would look much cleaner. I didn't know if this would have a large impact on operation or not.

A quick look in the Handbook will show you that the feed line is suppose to be
perpendicular to the dipole
BUT,
I think you should put it up like you described and then report back on the kind of results
you get.

Hi Doug
If you're going to do that why not just make a coaxial antenna?
Peel back 20 feet of braid over the coax and add a 20 foot wire to the end
of the center conductor.
Forget the balun. Use a tuner.
I think dressing the feedline next to a radiator is problematic at best.
Just my 2 cents.......

I saw an artical in a magazine once about doing something similar. The coax
was suspended a few inches below the dipole. I think but not sure that
somekind of choke was used on the coax near the end past the dipole to keep
the current off the outer portion of the coax.

My comments assume this is a transmitting antenna.

Doing such will essentially short out the balun - not a good idea
and virtually guaranteeing common-mode problems. It would essentially
turn the antenna into a horizontal sleeve antenna which is unbalanced.

Even with the coax hanging down, this antenna will be a poor
performer as the SWR on the coax will be high as reported by
EZNEC. 40m 5:1, 30m 9:1, 20m 14:1, 17m 8:1, 15m 15:1, 12m 22:1,
10m 21:1. The free demo version of EZNEC is available from

http://www.eznec.com

My advice is to feed this antenna with 300 ohm balanced feedline
through a 1:1 choke at the antenna tuner.

Thanks for all the input. This is the antenna I was planning to put up:
http://www.packetradio.com/windom.htm

1827. Ideas for a home built 2meter/440 dual band base antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-15 15:02:38 UTC
From: "Ralph Blach"
Message-ID: <10huuo8a91fkn72@corp.supernews.com>

Does anybody have any good ideas for a good dual band
2 meter/440 antenna? This would be a base antenna and
should be capable of handling 200 watts.

Thanks

Chip

The above statement might be read as though there is a threshold voltage limit above which a receiver will not deliver improved performance.

A receiver amplifies and detects whatever voltage is present at its input terminals, if just thermal noise. Even if no current flows in the input stage device itself, the wanted signal voltage present there should be as high as possible above the thermal noise voltage in order to maximise SNR.

Hello again,

Well, surprise, surprise...the thread deviates again! Hehe.

If i may add to the discussion:

By "reciprocity", a transmit antenna can also be used as
a receive antenna, assuming you want the same polar pattern.

A mismatch on the receive side will adversely affect the signal
to noise ratio, or would increase the noise factor of the system (which
is why you always want your low noise amplifiers as close to the
receive antenna as possible, usually mast-mounted, to avoid the
losses of a long coax).

However, at the very least, the mismatch on the receive side
will not result in catastrophic destruction of your output transistors,
which is what a mismatch on the output of a transmitter can result in.

So one mismatch is a bit more serious than the other.

Slick

Slick

I'd submit that, in a practical situation, the mismatch of an antenna for
receiving can be as high as 2:1 or even 3:1 without degrading the strength
of the received signal when the transmission line losses are low. I
thought that, if the receiver is tuneable, the actual impedance the
transmission line presents to the receiver can be 'accounted for. I
thought that, for a given antenna and transmission line, the effects of VSWR
are less important that for delivering power by a transmitter.
Am I wrong when I consider VSWR to be less important for receivers than
for transmitters?

Jerry

That was covered in another posting.

>Twenty years ago the USAF test data indicated that failure occurred at
>0.5 microjoules!!! That's 300,000 times more sensitive than your numbers.

Current USAF lore holds, rightly, that it is the power supply that
fulfills the failure, junction penetration energy is insufficient to
accomplish this. Turn off the equipment, disconnect leads and NOTHING
HAPPENS! Same pulse = no damage. Damage is not found in the
miniscule power it is found in poor practices.

Shielding is rather simple to accomplish, and taking care of front
door and back door paths is not Rocket Surgery. It takes very little
imagination to withstand these pulses; unfortunately it takes even
less imagination to succumb. The stories of 1 idiot's plight make the
news, not the 1 million survivors' success.

>Note, it is extremely difficult to really achieve a 0.001 ohm mechanical
>interconnect.

For you perhaps, and certainly others who experience lightning's
catastrophic failure, but 1mOhm is no big deal - measuring it is
however. It is simple to enumerate poor examples, but that does not
pass as careful accomplishment being impossible or unlikely.

>Secondly, the major electronic failure mode is from the coupling of the

>volts peak from one end of the wire to the next.

You are pencil whipping yourself, Dave. You are off by at least 1
order of magnitude in inductance.

As current USAF lore to this matter reveals (and it is nigh on to 25
years stale), huge pulse coupled currents at low frequencies do a
piss-poor job plain and simple.

Saying coupling and making it happen are two different things (per current USAF lore) and trying to fit 1MHz into a 1 foot wire is loath to considerably less potential. This is called overplaying your hand, a direct strike is enough to argue.

>would be performed under that constraint.
>
>Conclusion, lightning is a highly stressful environment.

Stress also encompasses primitive fear and probably far more so than the actuality of failure. This is called the probability of big numbers. In a nation of 280 Million, any individual's once in a million experience like lightning striking them or near them happens 280 times a year (5 times a week or more) - it misses the other 279,999,720 times tho'. Thus such hair raising stories inordinately color the topic and are suitable for selling insurance and amulets. Hence the advertising and $$$$$$ suggested retail cost for "peace of mind." At that price, if only 0.01% of those 279,999,720 pushed their credit cards across the counter, that makes for a very profitable living second only to ENRON.

Moral: "Don't use insulated towers."
Risk: "How well can you reduce R?"

Hi OM,

I can honestly say that an EMP can be generated by walking across a
wool carpet and touching a faucet handle. I could describe striking a
match as a conflagration or dropping a glass as a shattering
experience.

The term EMP is derived from a truly BIG event with truly BIG
consequences. Trying to elevate smaller examples and saying the
outcome is equal, is not honest at all. The nuclear EMP is orders of
magnitude higher in frequency and currents BOTH compared to lightning.
Saying that the EMP of lightning will cause the same disabilities has
been thoroughly discounted by sheer lack of evidence. We've had both
electronic gear and lightning for a long time, and no one noticed EMP
until they dropped The Bomb. Now, EMP is like sighting Elvis.

I have vaporized a screwdriver with far, far less current than
lightning has found its way unscathed through smaller radius wire.
The recitation of astounding numbers does not make an argument. Even
the Air Force's E-Bombs show they can eclipse lighting's current, to
no greater destruction (which was not particularly effective in the
first place).

An electromagnetic pulse can be generated by a time domain
reflectometer.

Depends upon the source of the noise. My 40m vertical couldn't
copy stations that gave me an RST of 559.

10W out of the antenna or 10W out of the transmitter? With a
T2FD, there is a very large difference on certain frequencies.

Hi Doug,

I'm Running the Windom (OFCD) it identical to what your saying. but
you'll find that the coax needs to come off the antenna in pretty much a
90 degree angle. ohterwise you will end up with lots of fedline
radiation which will cause problems in the shack.

A recent storm broke a limb over which one end of my 20 meter dipole was strung up. I also have a 10 meter dipole that I haven't been entirely happy with it's location. Since I have to put one end back up anyway...

I'm thinking of putting them side by side on the rope, as I have a lot of space between the trees. Something like:

Tree--Rope--20m--short_rope--10m--Rope--Tree

I only plan on operating one antenna at a time. Anyone forsee any problems with this layout? I was a tad worried about the lobes coming off the ends in the middle might have problems.

Oh, they will be about 40 to 45 feet off the ground.

Thanks,

Robert / N4IXT

We have to wait for the patent 'splaining the "miracle".
One thing I "discovered" that winding the wire either as a coil or simply
taping it to the wood or plastic dielectric detunes the heck of it (losses,
making it look more "broadband"). I taped the wire of quarter wave vertical to
the bamboo pole, and it was way off resonance. When I put plexiglass spacers,
insulators, bingo, right on frequency.
Coil is a coil and in the antenna circuit it behaves that way.
One thing is comapring quarter wave electrical length (loaded) radiator to
quarter wave monopole, another thing is making it electrically longer, loading
it and then comparing to quarter wave radiator. From presentation it was hard
to judge what exactly was DLM electrically equivalet to.

We might have clinic on verticals over "perfect" salty water soon, we are
closing on waterfront property near the Ocean Gate old AT&T huge Rhombic
antenna farm and looking for some juicy coiled sausage to BBQ.

I think that hanging cow bell and flourescent light on the DLM would make it
one class better, maybe 120% efficient antenna :-)

What will they think of next?

What I described, says it all. The variation from the helically wound coil at the bottom half of the radiator is the trombone like "coil" or loading stubs. Looks like one or two turn trombone loading stubs along the radiator. This should model in EZnec and show how the current decreases. Not much different from the loading coil at the base, which any mobile aficionado knows is the worst place to put the loading coil at.
Again. It is vertical, working against radials, or screen, loaded at the base with helical coil or trombone, then piece of tubing, then loading coil, than piece of tubing (stinger) or top hat. You can play with any sizes you like, it will not beat "classic" whip with loading coil about 2/3 up the radiator.

When the patent is issued and published, you will be able to see where the "secret" is. He promised to have something on the web site, but I did not bother to take a note of it.

It sounds like you (and some other posters) might be confusing the transmission line SWR with the impedance seen by the transmitter/receiver, which is often indicated with an SWR meter. The two aren't the same.

Consider, for example, a 50 ohm antenna and 50 ohm tx/rx, with a 300 ohm half wavelength transmission line connecting the two. The antenna sees a perfect match (50 ohms) when receiving, and the transmitter sees a perfect match (50 ohms) when transmitting. The transmission line SWR is 6:1 when transmitting and receiving. On the other hand, if the antenna and transmission line are both 300 ohms (+ j0), the line SWR will be 1:1 when transmitting, 6:1 when receiving. And so forth.

The effects of impedance mismatch seen by the transmitter when transmitting, the impedance mismatch seen by the antenna when receiving, and the transmission line SWR are three separate issues. Each has its own effect on system performance, and each needs to be treated separately. The importance of one or the other depends on the individual situation.

Yuri
What I find hard to understand is that the University has placed its name behind it.!
The professors at the university had years to review the design and I presume stood behing it.
I also understand that actual measurements were taken albiet possibly with misuse of equipment..
I also find it odd that the ARRL did not get a jump on it before today as the inventor has connections with them.
and wide spread notice that he also was a ham. FCC is probably snickering now about ham operator statments
including those of the ARRL comments regarding use of power lines
Its a shame that the ARRL will take a laid back aproach on this antenna until they have had a chance
to review comments from elswhere. There must be something that was missed at the show possibly because of
a prior belief that it was a fake regardless of what he said. In the mean time I accept your analysis sinc eyou were there as was Chip.
Hopefully Tom W8TI was there and jotted down drawings from the' how to make' session so that he can point
out errors and falacies in the analysis from the first session where many graphs were presented of the findings
and possibly the technology behind it
Regards
Art

Operating an independent 10 meter diople in the near vicinity of a 20 meter
dipole will slightly affect the radiation patterns of both. There's no way
of detecting any differences from normal.

Reg, G4FGQ

Roy

It might be that I'm wrong with my conclusion that when receiving, the loss of received signal wont be appreciably worsened by VSWRs as high as, say, 3:1, when the line atenuation is under a couple DB. But I dont think I've been confused about the Line to Load Mismatch and VSWR.

I recognize that the lowest VSWR and lowest line loss and the lowest noise figure are all important.

Since I'm always working with systems that arent perfect, I dont get concerned with low VSWR when working with receivers except when there is need for phasing arrays. It is my understanding that the transmission line loss isnt increased excessively when the line loss is under about 2 DB and the VSWR is as high as 3:1, and that S-meter readings arent measureably degraded when the receiver sees these signals thats not coming in with a 50 ohm internal impedance.

It occurred to me that the original poster of this "Phasing Harness" might have some sophisticated need for phase or low mismatch. If the two antennas being harnessed are only to maximize radiation toward the horizon, I'd consider the question a simple one to answer. ie Feed them in phase with any convenient equal lengths of line. If bandwidth is a factor, expect sidelobes to vary with frequency.

But, my knowledge and experience is very limited, so any 'redirection' of my thinking is appreciated.

Jerry

Hi Jerry,

It seems your question isn't going to be answered except to three
decimal places.

You are right, no one will notice much difference to mismatches such
as you describe. I know that your interest is in satellite plots of
weather conditions. You may experience some drop out - snow in the
picture. However this would be for marginal signals, and I am sure
that the uncorrelated noise would only slightly degrade the contrast
or detail.

I've played with WEFAX over HF to worse conditions and those pictures
came out quite readable.

'corse, from this "troublemaker", on VHF, (and granted, the noise figure of a reciever , or preamp is less compromised by swr, THE FURTHER from the SOURCE(antenna), because of the loss's in that line (great dummy load for 432: 200 foot of rg-58u, don't even terminate it! If a Bird reads ANY swr,meter has a problem (because of the loss)! But, then look at the loss's from the standpoint of a (Scatter, Moonbounce, Long Distance VHF (ect)) Operator, trying for the "HOLY GRAIL" of a BI-DIRECTIONAL 20 + dB gain, noise figure of less than , say 1.3 dB (sky noise), and a KW ,+ Minimum FEED LOSS'S, on 2 meters to hear your own echos. When at THAT point, and keep in mind:
1) that when stacking antennas, the MAXIMUM (maybe you know different) GAIN accomplished on a bay, is 3 dB , for 2 antennas, 6dB, for 4 antennas,ect., 2) that The Reciever front end, Maximized for BEST NOISE FIGURE, is adjusted to the that point, by intentionally MISADJUSTING the front end impedence, to obtain THAT optimum point,at 50 OHMS!
and 3) that anything that is misadjusted, to add ANY LOSS's to the system means the difference (because bad stacking distances, mis- fed coax(out of phase), change in the front end impedence of the LNA, ect.) means the difference between sucess,or failure!! Perhaps was wrong on initial assumption that swr was bi-directional, but doesn't negate the original premise that the swr has no effect on recieve-- and, btw, will the stacking actually provide THAT 3dB?? (before, or after the added 3:1 mismatch)?? Yours for comment?? Jim NN7K

Institution or magazine is only as good as people in it. Obviously UofRI does not have RF department, otherwise the technician would not be the star "inventor", if they had even dummy like me, that would not fly out into the press release and patent office. (Well, you can patent anything now a days, but why waste money, unless you expect to fool some clueless buyers.)

ARRL and QST is slipping in quality and reviewing what goes out. See the wrong "wisdom" of distribution of current in the loading coils that was started by Belrose in the 50ies and propagated through Compendia and ARRL Antenna book and defended by W8JI till this modern times. There are more half baked articles showing up with time. Internet helps to discuss and correct some stuff, but seems that with time, we are getting more "experts" discovering perpetuum mobile and getting away with it.

Good thing it is only a hobby and some bright minds are still around at this NG :-)

In the _far_field_ the dipole would have a null in the direction of
the wire and thus, the connection between the dipoles would be
minimal.

If short_rope is much less than a wavelength, there are going to be
some near field influence on each other. Looking at the 14 MHz dipole
and ignoring the 14 MHz feedline for a while, there are two 5 m long
elements that are a half wavelength on 28 MHz, thus they are resonant
at 28 MHz.

...5m_section--X--isolator--Y--5m_section--short_rope--28MHz_dipole...

Since power is transferred via the near field, these two sections will
also reradiate and will work as additional point sources distorting
the radiation patterns into some directions. Depending on how tight
the coupling is between the 14 and 28MHz dipoles, this might or might
not be a problem.

Now look at the two 5 m sections of the 14 MHz dipole at 28 MHz. There
is a feedline connection at the right end of the leftmost section (X)
and also at the left end of the rightmost section (Y). Since the ends
of a half wave segment are the high impedance points and if some lossy
low impedance feeding arrangements as used (such as baluns, coax and
unpowered transmitters), some of the 28 MHz power transferred to the
20 m dipole is dissipated in these losses and not reradiated. This
will clean up the 28 MHz dipole pattern somewhat, but some transmitter
power is lost as heat in the 14 MHz dipole feed system.

A balanced open wire feed to the 14 MHz antenna with open circuit in
the shack should have minimal effect on the losses on 28 MHz, since
the power would simply be reflected back from the open end and
reradiated later on.

As long as we make sure the readers understand we're talking about the actual SWR on the transmission line, that's true for both transmitting and receiving.

> I recognize that the lowest VSWR and lowest line loss and the lowest noise
> figure are all important.

If the VSWR and (matched) line loss are roughly within the bounds you mentioned, the transmission line VSWR isn't really important, since the extra loss it causes is generally negligible. However, as I somewhat indirectly mentioned earlier, the match between the antenna and its load determine the amount of signal that gets to the receiver. And as Ian has mentioned, the receiver noise figure might be best when the receiver is mismatched to the source impedance it sees. Further qualifying the matter is the fact that at HF, losing signal when receiving due to mismatch, line loss or SWR doesn't impact the signal/noise ratio unless the attenuation is very great, since the dominant atmospheric noise is attenuated by the same factor. I do realize, though, that the original posting was directed toward VHF or above, where those things do matter.

Thanks for all the replies!

It sounds as though if I keep "short_rope" over one wavelength in length
(which I can do), that would do the best job of minimizing loss.

Yuri

Does this antenna have an upper limit on the frequency it'll operate at?
I'd think some real life data on efficiency could be derived from enclosing
anantenna in a 'big enough' styrofoam cooler type enclosure. If the parts
that *I* suspect to be lossy might cause a significant temperature rise with
several hundred watts fed to the antenna.

1866. What is RF current?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-16 16:08:46 UTC
From: krt2054@charter.net
Message-ID: <33d49c4.0408160808.1e1595c7@posting.google.com>
Source record: 90887

Sorry for the dumb question, but I see the phrase "RF current" used in so many contexts that I am not sure what it is.

What I "think" it is, is:

1. The sinusoidal, voltage / current that is impressed on the, e.g., coax feedline's center conductor by the transmitter (a.k.a., generator)

2. The voltage / current on the conductive portion of the radiator

3. The sinusoidal, voltage / current that is picked up by the "other" conductive portion of the radiator (e.g., other pole of a dipole or the ground, radials or counterpoise system of a vertical antenna)

4. The sinusoidal, voltage / current that is returned to the transmitter via the shield of the coax.

5. The induced voltage / current in the counterpart of the receiving system.

6. The current that "flows" in a dielectric, otherwise known as displacement current, the original notion that allowed Maxwell to posit the existence of the ether.

That is, RF current is no difference than "current" except for its frequency.

What RF current is NOT is the transverse electromagnetic wave. That is, once the effect is in the ether there is no RF current.

Looking for confirmation or refutation of the specific points above.

Thanks.

Thomas

There is no limit on the operating frequency of any antenna. If you can feed RF into it, it will radiate. Question is where, pattern is determined by the electrical length of the radiator.
The real efficiency of shortened antenna should be indicated by the comparison with full size equivalent (or any other known type) and measured field strength, like it is done in mobile antenna shootouts.
Any RF energy lost in heat is not radiated and will show up in lower signal levels. It is important to compare antennas with the same radiation pattern and ground system.

Richard, I think he is just too close for night time sky wave, and too far for ground wave. When I lived in western Ohio, I had no trouble picking up WABC with the built in loopstick. I have also picked up WABC in Bermuda and Florida. So, I don't doubt the 27 states coverage statement. I noiced I had trouble getting NY AM stations on the car radio in eastern PA.

BTW, You mentioned WJR. I can pick that up here in NJ, even though it is only 10 KHz from WABC, which is about 25 miles from me. All it takes is a receiver with *very* good selectivity. This is where the BC DX people bark up the wrong tree when they want more antenna gain. WLW (700) became problematic after WOR (710) went digital AM. They now broadcast hash at least +/- 20 KHz from the carrier.

Yuri

Youve gotten too refined. I mostly know about basic antenna theory and
modeling. But building a VHF model of a 40 meter antenna with #12 copper
wire wound around a 4 inch mandril might be impractical.
But, if the "wonder antenna" is small enough to be enclosed (mostly) in
something transparent to the RF but not to the thermal thats generated by
any I^2* R losses, wouldnt the temperture rise inside the enclosure give a
decent indication of efficiency?

If this "wonder antenna" designer claims to be able to shape the radiation
pattern with an antenna significantly shorter that a 1/4 wave stub, He
really has something. I suspect that the something he has is mental

illness.

I've been following this info on the RI antenna and have considered it to be so 'snake oilish' that it would never see the light of an auditorium.

Your post about attending the lecture made me wonder if anyone asked about *any* simple (approximations) measurements like the styrofoam radome to get some idea of the I^2*R power lost in the antenna. If he has an antenna, and a transmitter and enough room to build a foam igloo it seems that alot of data on efficiency could be obtained.
If I had any interest in describing an antenna I'd built, I'd at least use an infared thermometer on the section of the antenna suspected as being the most lossy.

Jerry

> T2FD, there is a very large difference on certain frequencies.

Out of the TX. I know that the lower you go, the warmer the pigeon sitting on the resistor will get.

I tested the small neons I have. I basically found two types, one that clips at 60V, the other at 110V. I made a classic 4:1 balun and soldered one 60V between each balanced arm and common. I know it's like wearing suspenders and belt, but I don't think they will hurt at under 10W.

Also, in view of what I read, I understand Richard's claim that a T2FD will snuff out much of the energy anyway:

- if the spectrum of the AC induced by a near hit is mostly in the LF to MF range, the resistor will indeed take most of the heat, just as if the power were coming from the coax

- moreover, as I sized the windings for 4MHz and up, the balun itself will short to ground much of the leftover energy it does receive from a near hit.

1876. Re: What is RF current?

Short response...

This pretty much describes what I think of when I hear the term. Current at a "high" frequency. An object for discussion will certainly turn out to be just when does the frequency get high enough to be considered RF and I will say that I think that depends on a lot of things, the first probably being wavelength, others being a matter of much discussion.

Verbose response...

Some pretty minor things...

RF Current, of course is the current, though you say "...voltage / current ..."

"sinusoidal"... If there are harmonics present, then there can be multiple sine waves and the resultant (superposition of them) won't look sinusoidal, but a sum of sines.

RE your #3:

I'd say that the current in a dipole (or ground plane, for that matter) is "pushed into" one side and "pulled out of" the other side (the sides alternating each half cycle) rather than being "picked up" by something considered to be an "other side". If the coax center conductor happens to be pushing at any given instant, then the shield is doing the accompanying pulling. If we view the dipole with a balanced feed line, then the push & pull may be easier to swallow. A dipole is balanced and there is a tendency to consider the coax shield to be at ground potential at all times. This is not correct and is at the root of a VERY large amount of discussion on these news groups...

An RF "circuit", if you will, requires two connections to the source, just like a bulb and battery. The rest of the "complete circuit" isn't as obvious with RF -- as you appear to understand.

I also suspect you MAY get some discussion on displacement current since it isn't being carried by the classical electrons-in-a-wire, but if the current is present on both sides of the displacement current medium (say, a capacitor dielectric), then there certainly must be RF current getting through it somehow, so to speak.

RE the EM wave. I also think this is correct. You have the fields present as though the voltages and currents were doing their thing, but there ain't no electrons in space. This is a fascinating symbiotic (sp) relationship, indeed...

Gentlemen
I have in the past alluded not only radiation from a straight element but also the ADDITION of radiation
occuring from a bent element. Nobody has commented on the authentisity of this statement and I have not come acros anything in my own collection of books.
Now my present antenna consists of various loops connected in both a clockwise and clockwise radiation form such that the circular polarisation cancells leaving pure vertical polarisation.. The loops are separatred in a way that intercapacity of the spiral loops is reduced as well as circular cancellation All of this is based on my gut feeling that R.F.current flowing around a circular radiating element. What I ask for for those who have a deeper background of R.F. is verification of my assumption
that extra radiation becomes available.
Appreciate any comments on this irregular aproach as I cxannot find guidance in the books.
A serious question regarding added radiation from an element in the hope that insight is provided even tho it may expose the fallacy of my aproach.
Thanks in advance
Art

Hi Jim,

My experience in the very short wavelengths is confined to RADAR. I have not pursued satellite nor EME. RADAR comes with its own compensations in that if you have one, you can afford to do it right the first time (I pine for the day when the FCC allows Amateur RADAR operation).

As for Transmit/Receive, they are so intimately wed, that it is sometimes difficult to separate them and judge their needs on their own merits. A Receiver doesn't need to have an input Z of 50 Ohms, but given that the Receiver of a Transceiver shares the same path ways of the transmitter, it is foolish to go a different direction. Why would you put a 300 Ohm first RF stage after a filter designed for 50 Ohms? A 6:1 SWR from the get-go is simply stupid when you can do it right with so little effort.

I've seen some discussion that it doesn't matter because front ends only take voltage and need no current. This is a 0Hz analysis and at 10MHz is thoroughly dead in the water. Stray capacitance negates any claims to an input being Hi-Z and the whole point of low Z inputs is to swamp nature's capacity to send your signal straight to ground before it sees that amplifier.

For the mild SWRs such as described by Jerry, most receivers have a lot of head room (capacity) to amplify what makes its way in. The only down-side is degrading S+N/N ratio for very small signals where this capacity fails to make up for information loss.

Source record: 90899

I have a low-power 4:1 toroid balun almost ready in a little plastic box. In order to keep the rain out, I am sealing everything up, but I am also considering space-filling materials.

I am leaning toward filling it with hot "wax" - actually, paraffin from standard household candles, although a harder grade like sometimes found in old military equipment should be better.

The pro should be that the box would not become sealed for eternity in case I want to re-wire something in the future, while epoxy is bomb proof, and urethane foam is also rather hard to remove.

Is there any electrical con to be considered?

All alternating current seeks to escape out into the void of space. Frequency merely tailors how effectively this is accomplished. Current arises through the movement of charge (fairly built into a physical process). This movement can be quite far away (even to the point of the Butterfly effect) but still influence other physical charges to mimic the movement. Hence there is the appearance of continuity of the current even though there is no physical transport capable of conducting that physical charge across that space.

In any current, if you could isolate and observe a specific, physical charge; then you would observe that it travels no more than a meter a second (if that fast). However, if you could isolate and observe two specific, physical charges; then you could observe that when one moved, the other would mimic that movement with nearly no delay and the effect of that continuity is only limited by the speed of light and the distance between those charges.

Loss won't be a problem. The effects of coupling will be a change in the feedpoint impedance of the driven antenna, and a change in the radiation pattern. Because the coupling between collinear elements is relatively weak, all you're likely to notice is that the higher frequency antenna might require a little adjustment from its calculated length in order to achieve resonance.

There's a fundamental problem in making a scale model of an antenna to determine loss -- the wire conductivity has to be scaled with frequency. Of course, the wire diameter can be changed from the normally scaled size in order to create the same loss, but then the antenna might behave differently.

It's not clear to me how you could get quantitative data from measurements in a styrofoam container. Let's say you put 100 watts into the antenna for five minutes and the temperature rise (of the coil? helical winding? air?) was 10 degrees C. How would you calculate the loss or efficiency from that information?

No, current is not "voltage/current". It's current. Voltage is something else. This comment applies to 2-5 also.

It also doesn't have to be sinusoidal.

And the fact that it can "flow" through non-conductors as a "displacement current". This can make its behavior a lot different than zero-frequency current (DC).

>
> What RF current is NOT is the transverse electromagnetic wave. That
> is, once the effect is in the ether there is no RF current.

"Displacement current" IS an electromagnetic field. It's the mechanism which induces conductive current in one conductor as a result of conductive current in another. (This the answer to the question I asked after point 3.)

Hi OM,

It increases the input to output capacity (reduces isolation).

Use the lid to keep the rain out. Invest your time in its seal.

If you want a hard, hard wax, visit a dental supplier, or a nearby
laboratory. They use very hard waxes for investment molds. Or they
used to....

Hi Art,

Extra? From where? What is the source? If it is the same source,
then it is not Extra, but simply managed to fit a need. In this sense
you still have to balance the budget of what you got, and what you
radiate and what you lose (to heat). The budget does not allow
Extras. The budget does however allow you to transfer balances as
long as you maintain the same total. In this sense, it is like
stacking elements with the correct phase relationships to move
radiation that would have gone to the clouds, towards the horizon.
You are still radiating the same power, but the relationship change
has netted more of it going in a direction more suitable to your
needs.

Now, as to the matter of bends in the antenna doing this; then the
literature is rich in examples to this matter. The Franklin antenna
comes to mind. It has lots of bends specifically tailored to create
this budget shift. It has been around for 70 or 80 years?

It does not. If you apply 100 watts to an antenna, 100 watts is
available to radiate, less any amount dissipated as heat. This applies
to EVERY antenna, from a rubber duckie to a zillion-element Yagi with a
boom you can walk on. No bending, adding of elements, supergain, loops,
or magic will give you any "extra radiation" above that. All you can do
with all the possible tricks there are is to concentrate some of that
100 watts in some directions at the expense of others.

> Appreciate any comments on this irregular aproach as I cxannot find guidance

My statement above is based on the law of conservation of energy, which
it sounds like you're trying to violate. If you think it's possible,
you'd make a lot more money by putting your effort into developing a
perpetual motion machine.

Roy

I'm a real slopy builder. So, I do alot of half-assed things. I might begin with a 100 watt light bulb inside the "icebox" to establish a referance temperature. maybe even a 50 watt and even a 25 watt. And, if the antenna could be modeled at some frequency where I could build an ice box thats sufficiently transparent to RF, like 6 Meters, I'd build a full size antenna for use as a referance.

I've never done something like this. It just sems very practical, since a 100% efficient antenna wouldnt introduce any heat. But , a 50% efficient one might produce about the same heat as a 50 watt light bulb.

I'd not declare this "ice box" to be a Lab Standard. But, if there was need, I'd sure try to evaluate the concept.

When people like you cast doubt on anything I tink up, I begin to doubt myself.

Points raised noticed and placed in my thoughts bag to digest.
With respect to radiation I revolve solidly about accedleratio during a point in time, accelleration required to negotiat a turn which even at constant speed create acceleration and lastly arangements that create more current without the loss of energy of which I see as coupling. Since I am pretty much self taught because of a loss of memory onslaught it is easy to build on sand without a true geoligists report which is not available when one works alone. Thus I am curious as to where exactly I have gone astray by not having a thorough education in R.F. workings. So if there is cycliic increases of radiation per unit length then I see the same unit length in spiral form introduces an addition vector of forces that I translate into radiation, I have a history of not being able to adequately explaining my thought so hopefully the above will assist in explaining my thought processes even tho they may seem totally rediculus to those edu8cated in the field of whom I ask for correction.
From how I see it I have not viotated any laws with this thinking but now is the time for me to put things in there proper place.and accepted without rancour.
Regards
Art

Yes Richard the literature does abound with bent antennas, even yagis to
obtain a particular performance.
I know that there are "curls" in fields and waves analysis
but I view travering a circle at a constantspeed as generation of a force
vector as in centrifugal force which I probably falsly have placed in the
radiation category.
If I am incorrect I need to understand why so that I can rebuild my thought
processes. Modelling the antenna
shows insights that i had not realised before causing me to make an actual
antenna for follow up.
Regards
Art

Hi Dick -

Thanks for passing along this very bad news. It is sad to lose
a fine OM like Bill, under any circumstances.

But all of us with an interest in wire antennas will be markedly
poorer because of this. IMHO, Bill's antennas were not merely
the best on the market; they were more numerous and better than
than all the competitors that I know of, COMBINED!

So this is a big, big hit for those who enjoyed the convenience
of buying turn-key, well-engineered, multi-band wire antennas.

I'm very glad I have my two W9INN multi-band dipoles--but
I'm very sorry I won't be able to replace them, or add to the "farm."

RIP, Bill. Thanks so much for increasing my enjoyment of the hobby.

73, Ed W6LOL

No need for that really, too cumbersome. If you measure R you can calculate losses due to dissipation in heat.

Again, real comparison of efficiency of shortened antenna is to compare against the same pattern producing full (electrical) length antenna, everything is included in what you would measure. Much simpler too. I can build quarter wave vertical faster than styrofoam igloo. :-)

Basic rules are, best inductive loading is about 2/3 up the radiator, coil is better than loading stub, top hat is the best. Anything else is jocker's attempt at perpetuum mobile.

It would if the thermal mass of the antenna were the same as the light bulb, and if the thermal loss through the wiring were the same for the antenna as for the light bulb. But otherwise, they could be vastly different.

> I'd not declare this "ice box" to be a Lab Standard. But, if there was

Well, then I've done a good service. Only when you have doubts about your methodolgy will you have any incentive to take the time to try and understand what you're doing.

Any conclusions you reach about the antenna's efficiency (except that it's not 100% efficient - duh) will be completely worthless unless you get at least some kind of handle on the relationship between the heat and the temperature.

The law of conservation of energy is a touchstone you should always use as a reality check for whatever theory you have. If your theory leads to a conclusion that contradicts that law, then either your theory is wrong or there was an error in some step along the way from the theory to the conclusion.

Or you belong to the perpetual motion machine crowd.

90 degrees under the antenna, not perpendicular at it's elevation. Get as
far away as possible, burying the feedline so your earlier dilemma will not
be worsened ;-)

I know my wife just _loves_ seeing that feedline "drop out of the sky" in
the middle of the lawn. But that's the way the antenna is designed. Suggest
you try that, determine it's efficiency by whatever means you can, then try

running it straight over to the house. I think we all agree it will lose some output power back onto the feedline, but you could handle the safety issue there, or try, with some RadioWorks line isolator products.

I'd be very worried with all those poor connections at every link point.
Could be (could) be a really good noise source. It seems that any movement
would cause changes in the current path creating noise on the Rx AND _your_
Tx signal. I fought similar problems on mobile phone installations. The
Appollo pick up ships had similar problems from the chain deck railing
parts. Good luck.

Now that analysis really *is* dead in the water!

My simplification to "the amplifier takes what it needs from a 50-ohm source" is just that - a simplification. But it is based on actually knowing something about the subject. If you wish to discuss input network design for FET RF stages in terms of Smith-chart circles of constant gain and noise figure, and the device manufacturer's quoted data for gamma-opt, then I'm willing and able.

Hi Art,

Because "Extra" in the budget does not balance.

If you get more power OUT because it is going in a circle, then you
FIRST have to put more power IN to get into that same circle. There
is no extra left.

"Tam/WB2TT" wrote re WABC night time reception in PA:
> Richard, I think he is just too close for night time sky wave,
> and too far for ground wave.

Quoting the original post, "I live approx 80 miles from the xmitter of station WABC (New York) 50,000 watts. During the day my reception is good-to-very good. After sunset however, the signal is poor to unlistenable -- due to fading and man-made QRM."

WABC radiates the same power from the same radiator 24 hours a day, and provides good daytime reception at this receive location, so it is not too far for the groundwave.

The ground wave is more or less constant day and night, so it is likely that the poor/unlistenable signal there at night must be the result of interference to the groundwave from whatever high-angle skywave WABC produces, plus the higher co- and adjacent-channel interference usually present at night.

I sure disagree about being able to determine an antenna's efficiency by either resistance measurements or by measuring received signa;l strength at any one point in space. But, you are certainly a much smarter fuy than I ever was. So, I am not equipped to get into a news group contest.
It is my contention that the antenna under test's complete radiation pattern and field strength would have to be measured and integrated if field strength is used to determine it's efficiency. That could get coplicated.
It would have seemed to me that the loss in any "R" is dependent on the current flowing in it. And, I'd be concerned that any resonances could have higher circulating currents at the operating frequency.

If you can point out the errors in my convictions, I'd like to read about where I'm wrong.

The most intelligent, sensible and successful radio engineers make no attempt to measure antenna radiating efficiency. It never occurs to them to do so - they invariably calculate it.

It takes no longer than a couple of minutes on the back of a used envelope, using a pocket calculator. It is more accurate and is absolutely certain to be enormously less expensive.

But perhaps some old wife who cannot do simple arithmetic will find a fellow creature somewhere in Google who is reported as having attempted to measure it.

The real problem lies in the western world's educational system. Arithmetic has been neglected for far too long. It will take two generations to return to normal and dis-arm children who take loaded guns, even automatic weapons, to school. Never mind about tower blocks. As a priority, teachers must be protected from acts of terrorism.

But too late. Chinese and other Eastern countries' education, science, engineering and technology will have already acheived supremacy.

But why make a battle out of it? I'm sure the peaceful, generous, Chinese will be quite willing to share the products of their educational system.

Roy

Since I consider antenna efficiency difficult to measure accurately, I'd
be willing to try to measure it as carefully as *practical*. If that
required that the referance heater had a similar "thermal mass" to that of
the antenna under test, I could probably make a heater that did have a
thermal mass equivalent to that of the antenna.
But, I would propose that there is no easier way to actually measure an
antenna's efficiency than to measure the amount of power it turns into heat.
Thats a statement I cant back up, and I know it.

What is a better way to measure an antenna's efficiency??

Richard I need more explanation than that because power is somewhat
irrelevant.
Radiation in my mind (and I must be now worst off than I really thougt) is
accelleration and decelleration of current
which is certainly not power which in my mind is Isquared R. Thus if voltage
is increased current decreases
and therefore radiation decreases.(see effects of very close coupling of a
parallel circuit)
I really do not know where you are coming from, it seems so glib! This is
not meant in a demeaning way, I just
don't want to mix apples with oranges at this point in time. .
Current through a member travels at a constant speed but with cyclic
variations
in radiation. Travel in a circle is also at constant speed but with a
CONSTANT radiation per unit length.
Where exactly is the error in my logic? I suspect it has to do with relative
phase angles but I need it explained
in every day language
regards
Art

You can rest assured that you haven't violated the law of conservation of energy. Newton's laws aren't quite so absolute, so who knows, maybe you did bend one or another. You wouldn't be the first -- do a web search on "ultraviolet catastrophe".

Anyone should feel free to present a point of view. But if it contradicts the law of conservation of energy, it's wrong.

I recognize this as a commonplace expression in this group (not unique
to you by any means). It is one of the most ill-conceived statements
ever to come down the pike and your conundrum (as for others) in
trying to retrofit it into a theory is part and parcel to its poor
analogy.

>I need it explained
>in every day language

Hi Art,

The plain, every day language of budgets is there. If you cannot
balance that simple ledger, then you have scant chance of
understanding the larger enigma.

I used 3m 'Scotchkote' to coat the whole shebang - it waterproofs it ok
you can get it in the electrical section of Home Depot or Lowes, etc.
but both your suggestions sounds good - Silicone would be my chouce of the
2.
other things to try : 3M 'Scotchfil' (its like a rubber putty) then cover
with 3M 88 weatherproof tape.
and of course - we can't forget epoxy (but it will crack in time)

I believe it would usually be easier and more accurate to measure the amount of power it turns into radiation. That is, measure the strength of the radiated field compared with an antenna of known efficiency and preferably having a similar pattern.

Neither is easy, and a method that's "practical" from your point of view might well yield results which are so grossly inaccurate as to be useless. But go ahead, do a careful estimate of the accuracy you expect, do some measurements of various simple antennas whose loss is easy to calculate and compare the measured results, and see how well you can do. It's probably within the reach of a very careful amateur to make measurements which are accurate enough to be useful. It just isn't easy, and requires knowing the relationship between heat and temperature, where the heat is going, sources of error and the amount they can contribute, and a whole lot of care and attention to detail. And that's to get even crudely accurate results.

For myself, I'd model it as Reg suggests (although I'd use a program rather than the back of an envelope as he would) and easily believe that the model results are more accurate than any measurement I'd be able to make. However, neither calculation or measurement results are likely to alter the claims made by manufacturers of miracle antennas and their fans.

> What is a better way to measure an antenna's efficiency??

Hi Jerry,

I see you are suffering from answers out to three decimals again.

Your idea is not so far fetched, it is the simple calorimetric bomb.
With enough patience and references, yes, you could measure
inefficiency. However, the inefficiency could easily be lost in the
inaccuracy and patience is not a virtue where simpler methods prevail.

You rightly note that a total integration of all field strengths would
be required, and be far more cumbersome. This is the classic
treatment, but when done once with a reference for comparison, it is
unnecessary to apply to other antennas of simple characteristics.
Others note that simple comparisons serve quite suitably. For a small
antenna (that is, in relation to wavelength such as the DLM and others
like CFA/eh/fractals purport to operate efficiently in) there is no
hint that the radiation lobes are going to offer manifestly high gain
so as to drive comparisons off the chart. Certainly inventors make
such fantasy claims, and those claims characteristically remain
unsubstantiated. The DLM is a classic example.

Side by side comparisons of the DLM with known good antennas, or even
known poor ones with similar lobe patters could easily reveal
efficiency. I suppose these same inventors could crow about a razor
thin 24dB gain lobe pointed at the horizon (if you only knew the
tune-up procedures), but you are not going to find this from any
antenna packed into a box with less than quarterwave dimensions on all
sides. [readers: Examples proving this last sentence wrong are
welcome.]

> I sure disagree about being able to determine an antenna's efficiency by
>either resistance measurements or by measuring received signa;l strength at
>any one point in space.

From practical, engineer's point of view, and we are looking at shortened (loaded) antennas, you (or at least I) want to know how efficient the loaded antenna is vs. equivalent (same pattern producing) antenna. You want to compare oranges with oranges. The ultimate indicator is how much is one better (worst) than the other producing more (less) transmit (or receive) signal. That is the ultimate parameter that we are looking for, that's what you want to measure and compare. We have dB as a unit for that. 3dB means you gain (lose) double (power) signal. If you lose 50% in the heat, you will see corresponding loss in signal strength. So forget the igloo!

>But, you are certainly a much smarter fuy than I
>ever was. So, I am not equipped to get into a news group contest.

How did you arrive at that without putting me in the styrofoam igloo, or that I am Fuy? :-)

> It is my contention that the antenna under test's complete radiation
>pattern and field strength would have to be measured and integrated if
>field strength is used to determine it's efficiency. That could get
>coplicated.

NOT! That's why you want to use the same pattern producing antennas for comparison (apples to apples) i.e. quarter wave (electrical) shortened (loaded) vertical vs. full size quarter wave vertical made of same material (tubing). You can make measurements at the same point (properly chosen) and compare signal levels while swapping the antennas at the same test site.

> It would have seemed to me that the loss in any "R" is dependent on the
>current flowing in it. And, I'd be concerned that any resonances could have
>higher circulating currents at the operating frequency.
>

Circulating in what?

> If you can point out the errors in my convictions, I'd like to read about
>where I'm wrong.
>

You can be "convicted" in anything you like. But you have to look at the problems and see what are you trying to achieve. I always try to make antenna to produce the maximum signal in the desired direction, pattern. That's what you try to measure, evaluate. Anything else is just contributing factor that

gets included in the final parameter - signal strength. You can fart with heat, resistances, etc., I do not use antennas for heating, I use them for producing or extracting signals and that's what I am interested in and want to quantify. You need proper "standard" and use proper parameters to compare your "miracle" against.

If Mr. Vincent "discovers" that his shortened antenna is more broadband than full size (same electrical length) radiator, than he has some serious resistors "broadening" the response. My dummy load is perfect broadband "antenna" and almost 100% "efficient" - turns almost 100% of power into a heat, but radiates almost nothing.

The point is, you can measure other things like heat generated by the loses, but you are neglecting other parameters that come to play, leading you astray, while neglecting the most important parameter - the result you are (or I am) after - the signal strength!
Does that "convict" you? Otherwise I rest my case.

Art,
An interesting proposition. Acceleration of a radio wave.
If this succeeds, then does this mean that the wave travels 'faster' than
other waves?
If that's true - and the wave does travels faster - then it follows that the
length of the propogated wave would be shorter.
If the length is shorter - then we would perceive it as a shift in
frequency - because we assume all RF travels at the same speed.
For instance - if the wave 'started off' 2 meters long - and was accelerated
to double the speed, then the wavelength would be only one meter long.
Our assumptions may be invalid.
We can only base our responses on what we have learned, but if this is new,
then it folllows that we have not learned it yet.
Let's hear more about your theory.

can you put an antenna analyzer on it?
If you can estimate the dominant impedance, you would have a better idea of how to match it up.
I would be tempted to wind a 4-to-one balun on a toroid and put it at the end of the coax to feed the wire - but I would be guessing.

Roy

If I had your credentials, I'd measure antenna efficiency the way you prescribe.
It is only because I have no faith in my abiliuty to convince anyone what the pattern of a "New-Revolutionary is, that I'd get a thermometer out to chech my predictions that the antenna has *no* loss, like this guy does.

As I read this thread, there is one guy who thinks measuring the temperature of an antenna for getting information on its efficiency. And all the other posts consider that guy to be 'on the wrong path'. I'd advise doing it some way *other than* measuring heat of the antenna.

Jerry

You're too late -- the hyper-light-speed antenna has already been invented -- and patented. See U.S. patent #6,025,810. You'll have to do some splicing if the following link is broken by word wrap. Or it's easy to find at http://www.uspto.gov.

http://patft.uspto.gov/netacgi/nph-Parser?Sect1=PTO1&Sect2=HITOFF&d=PALL&p=1&u=/netahtml/srchnum.htm&r=1&f=G&l=50&s1=6025810.WKU.&OS=PN/6025810&RS=PN/6025810

Roy,
the link worked as-is
I saw a TV special (I think it was on Nova) talking about 'string theory' -
that antenna invention mentions mutliple dimensions - and so does the string
theory-
But they (nova) hypothesize that we would need 'gravity waves' (not EM
waves) to communicate into another dimension.

I'm using roughly 140 feet of end-fed wire. Coax runs from the shack
out to underneath the near end of the wire, where I have a 4:1 balun.
One side of the balun goes to the wire, the other side goes to a ground
rod. TS-940S, IC-746PRO, and IC-703 all manage to match it on all HF
bands with no trouble. Coax length is not critical, but the balun
seems to help quite a bit.

Source record: 90850

Hi Hal, nice to meet you
What I have is not really a prposition or a legitimate theory, it is just something that apears to be in error but I do not understand why so I wanted something we had to e4xplain in exams which came from first principles. It was basic pricipals that I was looking for wether it be a comparison of area under a current curve per unit length compared to area when applied to a circle or even possibly a mathematical analusis. Roys says I am in error and should accept it because he said so. He is knoweledgable but just his word is not good enough.
Richard came in with his bag of tricks with the introduction of "power" which if nothing is stated he is off and running with an augument on the net. Ofcourse I did not fall for it, Soooooo I am reconciled to the fact that
there is not enough pertinent knoweledge out there that can allow reasonable discussion.
Still I find no discrace in asking the question even tho it may advertise my own lack of knoweledge.
Note you referenced speed per unit length in terms of frequency where as I was refering to a constant speed
where the energy input should have transpire3d into acceleration buyt instead added another vector that like a race care going round a circular circuit. This is going at constant speed all the time with the foot hard nown on the accelorator to counteract centrifugal forces evidenced by a spray of dirt that continues at a consistent rate and not in cyclic form if one accelerates on a straight runway.
In both cases we have constant speeds but we also have a difference in phases. Enough said. I have typed up the program to check things out again which has amounted to 400 wire segments plus the use of 20 variables to gauge the distances between each succesive coils so I can build the darn thing again from scratch and thus satisfy myself
on the why's and where fores rather than partaking in what will become a slanging thread that occurs in a somewhat regular fashion. If I am remiss on missing an actual true posting that discusses in detaILwhat I was
asking for then please draw my attention to it as I seemed somehow to have missed it
Very best regards
Art

Yuri

I realize you are a smart and important guy who knows alot about electronucs. But, when you enter in a thread at this time with statements about defining "3 DB" I wonder if you think everyone else is supid except you. Whats the point of defining "3DB??
I used to work with some very good engineers who happened to think measuring measuring antenna heating was a fairly decent way of getting "loss" data on an antenna. I happen to think it is a good way to get some preliminary info on antenna loss.
So, when you tell me to "forget the igloo", you seem to have placed yourself in a position where you think you know how to evaluate antenna efficiency and that I dont. I dont think you are *that* smart.

> in every day language

Art, a single RF traveling-wave wire has a natural Z0 in the
ballpark of 600 ohms which sets the V/I (E/H field) ratio.
The feedpoint current and the current at any point on a
standing-wave antenna is the phasor sum of the forward current
and the reflected current. Vf/If and Vr/Ir remain in the
ballpark of 600 ohms but Vf+Vr and If+Ir vary up and down
the wire. The current is high at a 1/2WL dipole feedpoint
because If and Ir are in phase at that point. The current is
low at a 1WL dipole feedpoint because If and Ir are out of
phase at that point. But If is approximately the same for
both antennas and Ir is approximately the same for both antennas.

That's why the superposed If+Ir at the bottom of a loading
coil is not usually equal to the superposed If+Ir at the
top of a loading coil. Each of the two currents indeed has
close to a constant magnitude through the coil but the phases
of If and Ir are changing in opposite directions. Thus their
sums are different except for the special case where the
relative phase difference is equal at both ends of the coil.

But for understanding RF radiation, If is fairly constant
and Ir is fairly constant, and each of those currents cause
radiation. Thinking about a terminated Rhombic Vs an unterminated
Rhombic will separate the two processes out in your mind.

It is almost impossible to keep all moisture out. This will condense when
the temperature drops. Drill some very small drain holes in the bottom
(after you have sealed it the best you can).

Ok, so the acceleration is in the phase-shifting between the adjacent coils
?
If I interpret that correctly, then its not a 'real' acceleration, but a
simulated acceleration - much like using pulsating DC to generate simulated
AC.
If you could describe it in terms a normal dummy like myself could
understand or at least draw a better picture, your theory may be taken more
seriously.
You say Roy's word is not good enough - But Roy has demonstrated his
expertise in this area time and time again.
I come here to learn from folks like Roy - and to inject some of my own
thoughts from time to time.
You come to the group asking for comments - and you got them.
You did not speak in terms of technical details - so a reply using technical
details may not be deserved.
There is no disgrace in asking questions (like you said) - but rejecting
expert opinions can be seen as a disgrace in some instances.

1936. Is AM Radio Harmful?

Is AM Radio Harmful?
By Stephen Leahy

Story location: http://www.wired.com/news/medtech/0,1286,64579,00.html

02:00 AM Aug. 16, 2004 PT

Korean scientists have found that regions near AM radio-broadcasting towers had 70 percent more leukemia deaths than those without.

The study, to be published in an upcoming issue of the International Archives of Occupational and Environmental Health, also found that cancer deaths were 29 percent higher near such transmitters.

Two years ago an Italian study found death rates from leukemia increased dramatically for residents living within two miles of Vatican Radio's powerful array of transmitters in Rome.

The Koreans looked at the death rates in 10 regions with AM radio-transmitting towers broadcasting at more than 100 kilowatts and compared them with control areas without transmitters. The substantially higher cancer mortality in those who lived within two kilometers of the towers led researchers to conclude that more investigation was needed.

However, they also said their study did not prove a direct link between cancer and the transmitters.

"There have been many studies like these, and they aren't very convincing," said Mary McBride, an epidemiologist at the British Columbia Cancer Agency. Many other factors could have contributed to those cancer rates, said McBride, who has headed a number of similar studies and found no direct link.

Equally important is that studies in the lab don't show how radio waves can produce cancers, she said.

Debate continues over the health effects of radio waves from transmitters, both large and small, and other forms of electromagnetic fields, including power lines and microwaves.

Sam Milham, a Seattle-based epidemiologist and a pioneer in electromagnetic-field research, is convinced there are health effects. "Lots of research papers from around the world show increased cancers near transmitters, although TV and FM transmitters are more often implicated."

Moreover, many lab studies show low-frequency EMF disrupt living cells, Milham asserts. Critics like McBride say such results are often difficult to reproduce at other labs. Milham says that's because of differences in

the Earth's magnetic field and stray EMF.

In an attempt to settle some of this, California's Department of Health Services reviewed all the current studies of EMF risks from power lines, wiring and appliances in 2002. It found no conclusive evidence of harm. However, links to childhood leukemia, adult brain cancer and Lou Gehrig's disease could not be ruled out.

"I'm convinced that politics and corporate interests are behind denials (that say) there are no health effects," said Milham.

Meanwhile, the FDA and the World Health Organization are urging more studies, especially of radio waves from cell phones.

1937. NJQRP Squirt 80M antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-17 05:45:56 UTC
From: theplanters95@aol.comnospam
Message-ID: <20040817014556.23098.00003683@mb-m07.aol.com>
Source record: 90859

From April 2001, QST.

The NJQRP squirt is a 40M dipole with each leg at 34 ft, feed with 300 ohm twinlead for use on 80M. I'm thinking of putting one up, but using 450 ohm window line going to my trusty Dentron Jr. antenna tuner. How will this antenna perform on 75m-6m?

My guess is that since each leg is more than 1/2 wavelength on the bands above 20m, it will exhibit some gain. On 40m, it would be a dipole, and according to the article, will exhibit about 1 S unit (7.7 DB) with 300 ohmline of loss on 75/80m.

I do not have the means to model this antenna. The antenna will be between 10 and 20 feet high (I'm looking for NVIS for ARES on 75m & 40m). With these parameters, will the antenna be ok for DX on the higher bands? Is it an ok compromise until I put up a loop antenna? I'm just interested in getting a signal out!

Randy ka4nma

you can email me directly at theplanters95NOSPAM@aol.com, after making the neccessary correction.

1938. Re: Efficiency of radial system

Hi John,

There are claims and there are measurements (and there is even
software to make the claims for you). Stick with measurements.

If your vertical antenna qualifies as a thin wire radiator, it will
exhibit, at resonance, a certain resistive component - let's call it
37 Ohms (caveat: this varies with wire/tube size which in turn
impacts exactly how tall, how resistive, and how much Q the radiator
has at resonance).

The trick is to be able to measure this resistive component within an
Ohm or two (or five). You may be able to infer it through the use of
a SWR meter if no other methods are available, and this method may
provide enough data to move on.

If you measure that same 37 Ohms, guess what? you've done your best
and no more radials are required. However, chances are you will read
slightly more than 37 Ohms (or whatever the starting figure is for
your style of antenna - style meaning a thick or thin radiator).

If you measure in the vicinity of 50 Ohms, you can be sure that you
have an additional resistive component that is combining with the
radiation resistance - two resistors in series. One of those in
combination is that same 37 Ohms (with the usual caveat of style) and
the other is the loss of ground, or the loss of poor fittings (tighten
connections). This may be improved through the addition of more
radials.

However, in the pursuit of nirvana (or simply wanting to dress like
you've obtained nirvana), be advised that few, if any, will notice
your "improvement" whatever you do.

Another caution, you may even be tricked by the loss of the cable
going to the antenna. This loss subdues the actual SWR at the
radiator and presents a more modest reading at the transmitter. In
other words, an antenna exhibiting the classic 37 Ohms may appear to
be a faithful 50 Ohm match through the loss of transmission line.

So, what kind of data do you have to offer? Also describe how you performed the measurement and how remote the antenna is from where you made the measurement. Also, give a description of the area surrounding the antenna. Like, is it in the forest? Is it slapped up next to your house that has a metal roof? You know, interesting details like that which perturb the purity of science with the world's reality.

Hi

Is there a PRACTICAL way of measuring the the improved efficiency that a radial system brings to a ground mounted quarter wave vertical antenna?

I was wondering how my 30 radials over clay soil improve antenna efficiency. Are there any easy measurments that I can do?

Thanks

John

>
>
Well last time I had the radio in use was 1995. Found the problems I was
having was due to having the wrong microphone plugged into it.. Yes it does
have a battery that is still working after all this time. Once I got the
right microphone hooked up I discovered it still had all the local repeaters
programmed in just as I had put it away in'95. Still wary of the battery
though after all this time It could fail anytime now.. I have a scanner
board that uses a Super Capacitor to maintain memory I was wondering a bout
the feasability of replacing the battery with one of these. I cant find my
schematic for the radio so I have no idea what I would have to do to provide
a way of charging the cap.

In this case I would say no one have any information about this call sign on his page or there wasn't enough time for search engines to find it.
Any person who have takes any information about call signs, names, etc. in connection of a person in his page and any search engines will be able to found this periodical and write it to the database.

Regards

Ralf

Thank you all!

Here's what I intend to do:

- coat everything internally,
but without a space-filler

- seals

* fixed, for plugs and tieposts: a locally made silicone based strong
adhesive/sealant + external soft silicone coat

* reopenable, for the box lid: just soft silicone sealant

* wire tieposts & coax plug:
- soft silicone sealant, left to dry completely
- then wrapped in aluminum foil (no metal contact)
- then wrapped in friction tape, held in place by telephone twisted
pair;
it's another suspenders-and-belt trick I have used this to
weatherproof all sorts of antenna contacts, some lasting well over 10
years

This for keeping water out,
But, in case it does somehow get in, what about WEEP HOLES?

>loss or efficiency from that information?

First of all, the test should not be run for 5 minutes, but until a thermal equilibrium inside the container has been established, possibly mixing the air inside the container with a fan. This solves the thermal mass problems when equilibrium has been established. Measure the power fed to the antenna.

The temperature outside of the container should remain stable during the test. Then the temperature difference across the container wall is known, as well as the wall surface area and thickness and hopefully also the thermal conductivity for styrofoam (from the manufacturer). Now the thermal resistance of the container as well as the temperature difference is known and the power dissipation can be calculated. This is very similar to calculating the heatsink requirements for transistors.

If the thermal conductivity for the styrofoam is not known, run a predefined amount of power to the antenna until equilibrium has been reached and measure the temperature. Inside the container, disconnect the antenna, attach the feedline to a dummy load (possibly attaching it to some large metallic part of the antenna to act as a heatsink). Close the container and feed RF-power into the dummy load at an adjustable power level, until the same stable temperature is reached as with the actual antenna. Measure the power fed into the dummy load. This will eliminate the feedline conductivity problem as well as offset errors in the power meter (but not linearity errors).

This way the power dissipated by the dummy load is the same as the power dissipated in the antenna losses in the first place and thus, the efficiency can be calculated.

To avoid any power meter linearity problems, reconnect the antenna again, feed in the original full power and verify that there is a thermal equilibrium at the original temperature and outside temperature. Insert a calibrated step attenuator ahead of the power meter and adjust it until it reads the same value as in the dummy load test.

You can then read directly from the step attenuator, how many dBs the total full transmitter power was compared to the dummy load power which is also the antenna thermal dissipation value. A 10 dB setting would indicate that the thermal losses are only 10 % of the total power or 90 % antenna efficiency, a 3 dB reading would indicate that half of the power is radiated and the other half is dissipated in the antenna, thus 50 % efficiency. However, you would need a step attenuator with 0.1 steps to measure the worst antennas :-).

Many repeaters work perfectly well with 75 to 100 watts.

To get better coverage in and out, altitude is your best bet. Our
club's repeater (actually both of these bands) is on top of a 6 story
building, and others in the area are located even higher above mean
ground level.

Happy trails,

You win, I ain't so smart as I thought. :-)
I thought that antenna is supposed to radiate RF in the direction and with pattern one desires. That's what I want to measure, how effective radiator it is, how much RF it produces at the point of interest.
If you want to know how well it works as a heater, more power to you.
I am not in a pissing contest who is "smarter", I was trying to convey some practicality and what I do and what I am interested in.
Over and out!

>between groundwave and skywave?

Yes, that is what I have been writing in my posts on this subject line. The RF phase of the skywave varies independently from the ground wave. Some times it reinforces the ground wave; some times reduces it.

Further, both reinforcement and reduction can occur at the same time for different RF frequencies across the AM channel, leading to a selective combing effect in the program audio, and/or near loss of the carrier while most of the sidebands are still present. Of course, that produces very high distortion in an envelope detector. AM receivers using synchronous detectors reduce this problem.

Most full time 50kW AM broadcast stations use an antenna system with relatively low radiation at elevation angles above about 45 degrees in order to reduce (but not eliminate) night time interference to their own groundwave. I made up a simple graphic comparing the elevation patterns of vertical antennas used in AM broadcast for four different electrical heights: 90, 180, 195, and 225 degrees. The difference in their high-angle radiation is apparent. Please email me if you would like a copy.

No Richard I am not trolling I am very serious. At the same time I am always wary of any aproach by you
as the subject always get shifted and then we are off to the races.
Cecil pointed it out correctly with respect to power. If you were to solve a parallel circuit using complex circuit methyods the criteria is energy conservation
but where individual parts change their form of energy s we cannot glibly say that it revoves about
power or that I am referring to perpetual motion which is how Roy dismisses the thread but with no supporting data.
Now you say that accelleration and decellaration of protons are not the true basis for radiation
which certainly suggests that the subject is moot as the question starts off with a fallacy.

Dear Yuri:
The drawings are TIFF files. As I understand it, the Japanese
patent office was using TIFF and the US PTO just followed their usage.
In my opinion, PDF should have been used for everything.
So, one needs a reading-program that is able to display TIFF files.
I use Quick View Plus. A look here
http://www.uspto.gov/patft/help/images.htm
will find what the PTO describes as "free, unlimited TIFF plug-ins."

400 dpi PDF files would have been much better for everyone! Smaller
files, better looking pages, and searching capability.

Let us know how things worked out.

Well radiation is certainly a series of "pulses" as the radiation consists
of enclosed
waves and yet the speed of generation is constant and only the constituents
of total energy
undergo change. This is how I visualise creation of radiation on a straight
element.
Now we come to a element that is circular. I still see the generation
of radiation as generated on a strraight radiator but I now see that the
radiation has a component
as shown by a added vector as in centrifugal force which because the
radiator is circular
is constant. Now I am not proposing a new theory I am asking for a an
explanation why this is fallacious

Don't we all ? But sometimes Roy's words of wisdom does not satisfy the
questioner
asks for the underpinnings of the statement. Roy feels an answer from him is
all that is required
as in the word of God and he is not interested in trivialities and may even
leave the group for a while

I agree but a answer that states it does not obey natures laws if one cannot
supply the illustration on how it occurs
so any request for backup can easily be seen as rejection by some since the
words of God have been given>

==========

The known matching scheme is a tuner at the coax/antenna wire junction. For multi-band operation a balun is fairly useless.

But if you don't fancy walking 20 feet to re-tune every time you change frequency, reading the SWR meter with a telescope, why not do what I do. I just extend the antenna wire into the house using plastic insulated 18 gauge wire or something similar.

On the 160 and 80 meter bands you will notice no difference in performance or behaviour. Just a difference in tuner settings. On the 15 and 10 meter bands there might be an increase in RF inside the house over what you usually get. You always get SOME RF in the shack/house with end-fed antennas.

For an endfed wire you need a good ground near to the end of the antenna. When the end of the antenna is in the house the domestic plumbing system makes a very good ground. The hot and cold metal water pipes, with pipes to central heating radiators in each room, constitute an excellent set of long and thick "radials". It would be a great pity not to make use of them. Make 1, 2 or perhaps 3 connections from the transmitter to different nearest water pipes. Unobtrusive 18-gauge bare wire under carpets is fine. The transmitter will also pick up an RF ground via the 110V or 230V power wiring.

Of course that is what everyone would want to measure, but unless you
are working in the millimeter bands in a non-echoic chamber,
determining the true (absolute) radiation pattern can be quite
problematic.

You could fly around in a plane with a calibrated field strength meter
in trying to determine the true radiation pattern of the antenna.
However, the variations in ground conductivity may create a large
variations if the measurement is repeated at different places,
especially with unbalanced antennas.

Thus, it would help a lot, if the efficiency could be determined
separately from the radiation pattern, since much of the calibration
problems could be eliminated. The calorimetric method of measuring the
heat dissipated by the losses is one usable method to get the
efficiency.

If some manufacturer claims extraordinary _gain_ figures for some
LF/MF/HF antenna, you should publicly ask which plane was used for the
measurement and when were these measurements made. You can then check
the local airports, if that plain was in the air at that time.

Paul, simple approaches to calorimetry are, as you know, very difficult. Having done them extensively, I don't recommend radio amateurs try it, as the likelihood of missing even a second-order issue/factor is high.

Knowledge of Netwon's equations is essential vis a vis heating and cooling rates and equilibrium. (again, you know this; others might not.)

Since the DLM/DLD is a monochromatic antenna, it readily fits into a Wheeler cap approach for efficiency measurement. There was no data nor discussion of such an attempt in this veign.

There are no valid efficiency measurements of the DLM from the data I saw. If someone sees otherwise, kindly let us know and enlighten us.

Hi Paul,

First, you show that this is not an intractable problem, merely one
that requires care. Good work.

However, as to the statement above, and the presumptions that follow,
there is no equilibrium to observe as the test implementation has been
described. You are pouring calories into an insulated environment
which can only raise temperature without end (short of destruction, of
course).

As I described elsewhere, this is called a caloric bomb, and as such
should be limited in time for all comparisons. What you are
describing requires a steady flow of coolant through the chamber where
you measure the inlet and exhaust temperatures and use THAT
differential. Care must be given to not exhaust into the inlet, and
to maintain the inlet with a body of constant temperature air (to
simplify matters).

The problem is not really that difficult - it only takes attention to
detail such as your response indicates.

You just need a simple choke balun between the balanced ladder line and the unbalanced tuner.

A choke balun can be made by winding a pair of wires (like 18 or 16 gauge speaker cable) around a 2" diameter ferrite ring. 12 to 18 turns will do provided cable length on the ring is not longer than 1/10th wavelength at the highest frequency of use.

How it works is intuitively obvious.

Not knowing how you came to your conclusion no one can tell you why you are
wrong.. My uncle used to have a paint and body shop with a 57 Chevy up on a
pole in front of his shop. While the car would make an awful antenna it
would be futile to try to explain why. In another way of saying it would be
like explaining to a student how he missed a math problem when all he shows
is an answer. The best the instructor can do is tell him he is right or
wrong. In your case the instructor would not even be sure which problem he
had done.

Egad. Please go back and read my postings. All I've said is that you can't violate the law of conservation of energy. You shouldn't believe this fundamental principle because Roy says you should -- you should believe it because you've got a grasp of high school level physics, and if you don't have a grasp of high school level physics, perhaps you should get one before getting too carried away with theories about the nature of radiation.

Of course, ignorance is bliss. If you disbelieve or simply choose to ignore conservation of energy, you're then able to make perpetual motion machines and other wonders, including any number of miracle antennas.

And Art, quit whining that "Roy feels an answer from him is all that is required as in the word of God". What's required is that you take the effort to learn a little fundamental physics. I'm sure you can find an adequate explanation of the law of conservation of energy on the web if you have an aversion to books -- written by someone other than Roy. I'm not going to spoon-feed it to a reluctant learner.

1977. Dipole and Icom AH-4

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-17 16:55:34 UTC
From: Michael Melland <w9wis@charter.net>
Message-ID: <10i46v6dvmfff77@corp.supernews.com>
Source record: 90786

Anyone feeding a dipole with ladder line feed from an Icom AH-4 ?

I can find articles from people using it with whips and random length wires.... but I'd like to feed a dipole with ladder line from it.... one leg to the tuner's ground and the other leg the active tuner output. I think I would be able to float the tuner without a fixed "ground" connection then .... the non active leg acts like a counterpoise in a balanced antenna like this right (?).

While I do not believe you are trolling I can understand why others would
believe you are. I was not certain for a long time. The problem seems to be
a lack of common knowledge between you and those whom you are trying to
converse. To explain to you why you are wrong you first have to be educated
in antenna theory at least to an elementary degree. Unfortunately you tend
to reject the knowledge that other have learned over time, You read and try
to bend facts to fit your own preconceived ideas instead of taking them at
their face value. Frankly trying to explain something to you is so tedious
that most people just give up. If you truly want to learn you should try a

classroom environment. This is the wrong place to get all the information you want starting at the ground up.

Why AM?? FM is safe? What frequency is more to the point.
The human body is a very small portion of a wavelength below
1710 kHz, and it would difficult to couple a lot of energy into
one.

Art is obviously a well educated person having the ability to express himself in plain English better than most.

Unfortunately the technical content of his writings are pure gibberish, giving an intelligent reader the impression he is having his leg pulled - or being trolled. I cannot make any sense out of what he says and his reasoning. I gave up trying a long time ago.

As he so frequently admits, he is unable to understand what he himself is talking about.

(Incidentally, Richard, you have Art's characteristics reversed. But the end result is the same - too often I can't understand what it is you are waffling about.)

Art, may I suggest that before you write you think in QUANTITATIVE terms about what you want to say. Put some numbers and physical shape into it. Draw pictures. Solve your own problems. Go back to Ohm's Law and square 1. Otherwise you will continue to think in emotional terms without being able even to visualise, to picture, the subject matter.

Emotions and feelings are not a part of engineering except on pay-day. But the sheer beauty of deriving equations followed by logical calculation, especially when it gives the right answers, is something which no human should be deprived of.

As for Richard, old-man, there's no hope for you. ;o)

I suppose it might be possible to ask Google (and other major search
engines) to suppress lookups for your callsign.

However, anyone who knows how (and it isn't hard) can go to the FCC's
wireless-telecommunications site, and do a search on any FCC license
number (amateur, commercial, GMRS, you name it). As far as I know,
the FCC does not offer a service to conceal the information therein
from public view... and the FCC does provide regular "drops" of this
data to various sights (e.g. ARRL, QRZ, etc.)

My guess is that if you're a licensee, your data is "out there" to be
seen.

And, things which seem to be true, usually are.

My guess... looking at a Web-page description of the antenna and its "spilateral" technology, is that it's likely to behave like a compact omnidirectional antenna located in front of a single reflector. The dish is far too small to deliver a significant amount of focusing/gain as a parabolic reflector, at least at the lower VHF frequencies... it's barely a half-wavelength across. You might get a couple of dB of gain (relative to a dipole) but I don't think you'd get more.

Hmmm... in looking at the "goxium.com" web page, I observe that the description of this antenna says that it is "all-directional", compared to a "brand antenna" which is "directional", but the describive blurb claims that "The specially designed 'dish-like' parabolic reflector provides better directional and omni-directional grounding characteristics for ideal center-frequency tuning of local broadcast signals."

So... from what I can see, it's an omni, which means that it has little or no directional gain, which means that it's not well-suited for use in a weak-signal / deep-fringe area, or where multipath reflections from nearby mountains or buildings or trees tend to cause "ghosts" in the picture.

Seems like an expensive solution, compared to an ordinary roof-mount omni antenna having similar directional gain characteristics.

For your situation (I assume "cabin" means "quite a ways away from the city") you'll probably be happiest with a high-gain "deep fringe" VHF/UHF beam antenna (a log-periodic, with a corner-reflector for UHF). Mount it on a mast, as high as is practical. If the stations you want to receive aren't all in the same direction, consider adding a remote-controlled rotator.

Now that I think of it, my hairloss began sometime around my early
days in ham radio, and has progressed along with my time in the
hobby. Other side effects noted are that, as my friends will vouch,
I have become somewhat crazier, my eyesight is degraded, and my
joints have tightened up somewhat. One of these days I'm gonna
give up hamming... well, maybe! More study will be required.

1) Do NOT float the tuner, you will destroy the electronics. Grounding one side of a dipole won't affect it unless you have a low impeadence ground surface and a high impeadence antenna. Even then it will just skew your pattern.

2) I ran an Alinco version of that tuner to balanced line for several years. Worked well (I got the idea from an SGC publication). When I was later changing to a Johnson matchmatch box, I did some A / B comparisons and found that receive signal strength was higher on the Matchbox on some bands than it was on the unbalanced autotuner, but I had to look for the differences.

3) I tried a home made air core 1:1 balun in the line. It tuned but the signal strength was better with out the balun.

4) I fed both dipoles and loops this way.

Where may I see a drawing or description of this antenna (the NJQRP).

Thanks,
Butch KF5DE

Jimmy I know what the cuurent curve shows on a radiating element and I
suspect that you do also.
Now show me an equivalent current curve for a circle so I can see the
differences in area under the current curve.
Are they different or are they the same?. If you know where such a
comparison is shown and they are different
you are then positioned to inform me why.
By the same token if they are the same which is how most people see it then
I will be better able to
resolve my conundrum for myself.

> [...snip...] I was refering to a constant speed
> where the energy input should have transpire3d into acceleration buyt
> instead added another vector that like a race care going round a circular
> circuit. ...

Art,

First, I re-state your basic situation to see if I understand it:

You have a constant speed around a circle. This, indeed does suggest the normal radial acceleration (what is that... V/R^2 ? I don't remember). We know that acceleration is defined as a change in velocity, where velocity consists of both speed and direction. Speed being the distance traveled along a path per unit of time. So, if we change the velocity direction (to always be tangent to the circle) , but not the magnitude (or speed), then we have acceleration - what we call radial acceleration. I believe this all to be true. Are you with me this far and do I have your meaning correctly ?

Assuming the answers are yes, I continue to go into the part about energy "transpiring" into something.

You say:

"the energy input should have transpire3d(sic) into acceleration

buyt(sic) instead added another vector".

This appears to be saying that something (the acceleration) is _not_ produced by said energy ("should have...") , but rather something else _is_ produced ("...another vector").

The words you use in these two parts describe only one thing, yet you imply (by the words: "buyt instead") that they are different things. Radial acceleration is a vector directed toward the center of the circle. It is the 'radial acceleration vector'. Therefore, if your energy _DID_ "transpire" or more correctly, produce this "other vector" then it _DID_ indeed go to produce the acceleration -- because this vector _IS_ the acceleration. They are ways of talking about the same thing. I can't figure out what you mean.

Whether or not it takes energy to cause this circular acceleration is another matter I haven't addressed yet since the basic premises must be cleared up first.

I also think you are wondering if this radial acceleration does some special radiation that is different from the radiation of the charge simply by virtue of its 'normal' non circular movement. However that's also another issue, after we clarify the basics here.

Then you say:

"In both cases we have constant speeds but we also have

a difference in phases. "

You keep mentioning "constant speed" yet we are talking, I thought, about an antenna with RF current in it. If this is the case, there is _NO_ constant speed of the current. It is constantly varying in a sine wave. It has a sinusoidal speed variation and therefore a sinesiodal acceleration (acceleration being the derivative of velocity and cosine being the derivative of sine) So you seem to be applying two concepts (constant speed and . sinusoidal variation in speed) in one situation. I believe this is invalid and may be the source of your confusion.

Also, I don't know where this "phases" comes from. Lost me here unless you are talking about the relative phase of two different windings of this circular wire you mentioned a while ago...

Please explain what I have wrong, if the case.

> Enough said. I have typed up the program [...snip...]

What language are you programming in and what formulas are you using ?

Question mark?

Try this:
http://www.qrz.com/detail/XNZZZ
^^^^^...inserting the callsign.

If the reply is "The callsign XNZZZ was not found on our server.", then
the callsign was either never issued or expired A LONG TIME AGO.

Elsewise, just entering the callsign in Google will only reflect how
"busy" the op is on the web, in usenet, ... and/or in contests.
(I find my call often in contest logs that folks feel a need to post
on web sites....) I'm sure there are some grizzled olde (active)
op's that have never owned or used a computer (not even a Commodore 64),
and whose existance could not be proven by Google. (Google usually
does not index the pages given up by other "look-up" engines such as
QRZ.COM and BUCK.COM.)

Hi Henry

Can I ask a disassociated question concerning Search Engines?

If so, here is my question.

Most ISP subscribers have a home page usually named Index.html from this page they place links to their other pages stored at the website.

OK, Google can find all of these no problem.

But, if you place pages on the website that are not linked to your Index page that requires the person accessing your web site area to know the word or name to type behind the actual URL to get to this hidden web page, can Google find that page?

The reason I ask is that I have certain pages that are accessable only to those who need to know and know what to type behind the URL to get them to come up.
To the best of my knowledge, none of these hidden pages (not linked to the Index page) have ever been picked up by Google.
Naturally these types of pages bring up the directory instead of the home page if you click the back button, but the directory only shows a link to parent directory and clicking on that automatically brings up the index page, so the directory showing the hidden files supposedly cannot be seen.

How safe is this method?
And can Google find it?

You seem to assume that no thermal power will flow through the
styrofoam walls of the box.

Your statement is true if you insert a huge amount of power into the
box, in which case the temperature would climb, until the styrofoam
would melt. However, the measurement can be done at much lower power
levels that are compatible with the thermal conductivity of the
styrofoam.

If styrofoam would be an ideal isolator, you could put some deep
freeze food into a styrofoam box, move to your summer cottage and hope
that the food would still be eatable after a week. Unfortunately this
is not true :-(.

When doing antenna efficiency measurements, the power levels should be
set to a level, in which the temperature increase is manageable (below
the melting point of the styrofoam).

To give an example of the power levels required, assume that
you insert a 1 kg (1 liter) bottle of drink at 0 C into the test
container and after 10000 seconds (about 3 hours) the drink
temperature is at +10 C, the energy needed is about 40 kJ, thus the
leakage through the container walls would be about 4 W. With the
outside temperature of 20 C, the average temperature difference would
be 15 C and the thermal conductivity about 4 C/W. This is what you
usually get with some power transistors with a heat sink :-).

If you build an igloo around the "miracle" antenna, you should be able
to measure the heat generated (and thus efficiency) with power levels
well below the legal limit in most countries and with bad antennas
10-100 W should be enough.

Of course, you should make sure that the styrofoam own RF dissipation
is sufficiently small at the test frequency.

Generally Google or other search engines will not find pages that are not
linked. You can make sure that Google doesn't list it even if it does find
it by putting between the
tags.

We are looking at shortened, loaded verticals, monopoles. So you stick the "standard" - quarter wave radiator in the test point, measure it at proper point, then you replace it with "miracle" antenna and do the same, feeding them with the same power. The difference is in overall efficiency. Lets not lose sight of what are we talking about and what the real "problem" is.
How do you build igloo for 4 square? Comon guys, this is old stuff, has been done for 100 years already. Lets not fly off on tangents.
Is anyone out there who "calorimetered" the antenna?

Yes, the temperature will rise until the rate of heat leaving the container equals the power (rate of energy) entering the box. As the interior of the box gets hotter (more exactly, as the inside-outside temperature differential increases), heat exiting the box will increase. So at some internal temperature an equilibrium will be reached. You'd want to use a power level high enough to make this temperature well above ambient so that small variations in ambient temperature won't badly skew the results, but low enough that you don't cook the box's innards.

The method you propose seems workable, except I didn't see any mention of heat leaving the box via thermal conduction along the wires. Depending on the box's insulating property and the wires, this could be a significant contributor to the total heat loss from the box. Therefore it's very important to either insure that this loss is negligible compared to the loss through the styrofoam, or else to manage it (most easily by using exactly the same wires and wire orientation during calibration and test).

As I mentioned earlier, it's probably within the means of an amateur to make useful measurements, but it would take a lot of care and attention to detail. There may well be other factors none of us have considered (as examples, the presence of variable drafts in the vicinity of the box, which could impact the heat transfer rate in a major way, or nonlinearity of convective cooling), so measurements of various bodies of known dissipation would have to be measured to confirm that all significant factors are accounted for before there will be any confidence in the results.

Art
There is radiation due to the acceleration of bending a current, it's called
synchrotron radiation.
Synchrotron radiation and amateur radio have little or nothing to do with
one another.
Take elementary school science and report back.

Actually, your call sign is a matter of public record. Anybody can go
to one of several sites that allow you to look-up call signs. ARRL's
site does it. You can probably do it at the FCC's site.

Implicated but not proved. Have controlled animal studies been done? I think not.

Of course they cannot be ruled out because you cannot prove a negative.

> "I'm convinced that politics and corporate interests are behind denials

Nobody who understands science says there are no health effects. What they do say is that no health effects have been scientifically demonstrated. BIG difference.

> Meanwhile, the FDA and the World Health Organization are urging more
> studies, especially of radio waves from cell phones.

A good idea - if they are real scientific studies.

Some years back, there was a "study" done on cause-of-death of hams reported in the Silent Key column of QST. Researcher looked up the cause of death for a pretty large number of West Coast hams, and found somewhat higher frequency of death from certain cancers and leukemias. There was quite a buzz about it.

I did some digging and found a *bunch* of holes in the study:

- it compared West Coast hams to the general population, not to the West Coast population

- it looked only at hams reported in the SK column of QST

- it did not compensate for differences in age, occupation, or other environment factors like smoking that would have a big influence on disease. Nor did it research what sort of hamming the amateur did, or for how long. (The ham who did a little QRP for a few years as a senior citizen got as much weight in the study as the ham who'd run high power since teenage years and worked his entire career at a broadcast station, etc.)

- it found only minor elevations in the named diseases

- (this is the biggie) it found that there were some cancers and leukemias that were *less common* causes of death in the studied group. That little factoid was conveniently ignored in most media reports

- Most of all, the study repeatedly stated that it was not conclusive and that much more work needed to be done.

But we rarely hear "the rest of the story"..

Hi Jim,

That's simple. If you live close enough to the tower to start
smoking, then you have got one hell of a risk.

Dear Butch and Cecil;
It is good to get confirmation of such events from long ago.
Somehow, I also associate the year that it happened as being the year
when a postal card went from one cent to two cents. The new postal card
had a red square "stamp."
Anyone remember what year that would have been?
Oh. Even then, I was keen on antennas and radio. 73 Mac N8TT

I found this antenna to work very well on QRP. 34ft either side, inverted V at 30ft high and 45ft 300 ohm slotted ribbon is what I used as per the article. On 7mhz and above it worked VERY well and 3.5mhz was a little down but still very useable. I was using 5 watts or less, CW, RTTY, PSK & SSB. I now have it rolled up ready for portable work as I have more room for larger antenna now. Of course results depend on location but excellent performance for what it is.

However, scumbag crackers will continue to probe around in websites --
looking for any un-linked pages you may have. And, neither robots.txt,
nor will deter them.
Lately I've seen *concerted* probing efforts in my cgi-bin directory --
for things like contact.cgi, eforms.cgi, kontakt.pl, order.cgi, u.s.w.
All 'live' scripts found at _other_ web sites no doubt. (I've already
honey-potted the 'usual' scripts -- such as formmail.pl)

You can use .htaccess to restrict access to _just_ those ip's that you
wish to have access to the web pages. .htaccess is a server-side
control that the crackers can't (well, can't easily....) get around.

I use .htaccess and deep(er), totally bizzare sub-directory names to
try to prevent cracker access to some things. Of course, you need
to turn off directory indexing, too. And, avoid IIS...

But, what do/did either of these topics have to do with antennas?

Yes

This, indeed does suggest the
> normal radial acceleration (what is that... V/R^2 ? I don't remember).
Yes

We
> know that acceleration is defined as a change in velocity, where velocity
> consists of both speed and direction.
yes
Speed being the distance traveled
> along a path per unit of time
yes
. So, if we change the velocity direction (to
> always be tangent to the circle) , but not the magnitude (or speed), then
we
> have acceleration - what we call radial acceleration.

Not sure if I follow that.with respect to terms If what I said is what you
are saying
AOK

In the case of circular course constant speed energy must be inputed
to overcome radial force and ofcourse every action has an equal and opposite

reaction
I believe this all to
> be true. Are you with me this far and do I have your meaning correctly ?
It would appear so subject to my statements above
It would apear that it is so
>
>

_is_
> produced ("...another vector").

I am saying that energy is inputed to maintain constant speed which can be
seen
as creating a CONSTANT force vector at a tangent

>
> The words you use in these two parts describe only one thing, yet you
> imply (by the words: "buyt instead") that they are different things.
Yes because when the radiator is straight it is phase change that creates
cyclic
current change ala accelleration.
In the case of a circular radiator I understand that there is no phase
change
a nd the radiation vector is a constant. This may well be the nubb of the
misunderstanding.

Radial
> acceleration is a vector directed toward the center of the circle. It
is

simply
> by virtue of its 'normal' non circular movement. However that's also
> another issue, after we clarify the basics here.
That is correct in that current variation is constant in one case and cyclic
in the other
which inferes that over a cycle the area under the cyclic current curve is
the same as that seen
under a constant curren and it is this comparison that I was looking for in
literature.
>
>
>
> Then you say:
>
> "In both cases we have constant speeds but we also have
>
> a difference in phases. "
Yes I see the phase change as shown by the current curve.
and in the case of circular motion I do not see a phase change (I cos phi)
>
>
>
> You keep mentioning "constant speed" yet we are talking, I thought,
> about an antenna with RF current in it.

Yes

If this is the case, there is _NO_
> constant speed of the current. It is constantly varying in a sine wave.
> It has a sinusoidal speed variation and therefore a sinesiodal
acceleration
> (acceleration being the derivative of velocity and cosine being the
> derivative of sine)

Yes I agree. That would be of the value I cos phi with cos phi providing the
sign wave
I believe we are saying the same thing

So you seem to be applying two concepts (constant
> speed and . sinusoidal variation in speed) in one situation. I
believe
> this is invalid and may be the source of your confusion.

It may well be a difference of terms applied but I am pleased you follow
the main drift of what I was saying so you could be well armed to

correct me where I was wrong.
>

Steve it is a computor program that chooses or finds the best dimension for
an inputed variable.
plus can handle a large number of segments''''''
I have many circular radiators in a horizontal position but at different
heights.
All have a gap in the circle and half are wound in an opposite direction to
the other coils.
All of these loops are connected to each other by vertical members the
length of which depends
on the cosequtive height of the loops... These vertical portions become high
voltage and low current member
when requiring best efficiency. The impotant thing in this arrangement is
the correct selection of the up
then down positions of the loops for the feed input requirements.
You cannot research the best positions of the loops with Roy's program as it
is the basic of basics and
posibly not enough segments available but most programs of today DO offer
many variable dimensions
with more than enough segments (I used 20 segments for each loop)
I am very pleased that you connected the dots of my question which shows I
am not a troll.
My spelling is bad because this new computor has small letters on the screen
and with a
3 Gig Hz speed it is difficult to keep up to speed with a braille keyboard
Hi, Hi.
My very best regards to you and thanks for hanging in there as opposed to a
derogatory comment

You are, of course, joking. Why wouldn't you want an antenna that
handles at least that? 200 watts is low power on VHF and up for many of us.

I would expect any fixed antenna system I use on 6 or 2 to handle full
legal limit, and 70cm to handle 500 watts minimum. I will admit you
normally wouldn't use vertical polarization with that much power, but I
still want my antenna/feed systems to handle it without a problem.

In my original post I suggested using the same container and the same
cable to feed either the antenna or the dummy load. Thus the power
escaping through the feedline is the same in both cases and thus,
cancels out.

My suggestion of using a cold liquid and measuring how long it takes
until it gets warmer just helps to give a ballpark value of the
thermal conductivity, which will help to set the appropriate power
levels for the actual antenna/dymmy load tests, i.e. not too cold or
too warm.

No, I'm not joking at all.. We use repeaters here in Alaska that are on nice tall mountains all over the state. Check out the Arctic Amateur Radio Club repeater page sometime. Thier repeaters system has over 60,000 square miles of coverage.. I can access any of thier repeaters with a 5 watt handheld. My Icom 706 only has 10 watts on 2 meters and I've never had a problem with reception or transmission into a repeater.

I guess we're just not into the long distance contacts you outsiders like to do down there in the lower 48.

What's funny is, you can work satellites and space shuttles with 5 watts and a hand held Yagi... I still can't see the need for all that power on 2 meters.. I guess if I need to reach out farther, I go HF..

That's what makes this hobby so interesting though, we all have different interests.

Hi Mac,

It must've been quite an expense initially, later a bargain.

Let's see, all within reach I have some QSL cards from the mid 60's.
One from WLW at 4 cents, WCBS for a nickel, One from K7UGA also a
nickel and one from K4LIB, one from CBC for 3 cents Canadian, and a
post card with several cancellations marked Hamburg, Innsbruck, and
New York for One Cent (cancellations 1887) with an extra One Cent
stamp (for international?).

K7UGA would be livid with the crop of candy-ass, pansy republicans
that inhabit the hill these days.

Hi again Doug,

Was out of town so did not get your question for a few days.

You should run it away from the antenna at 90 degrees for about 1/4 wave
if possible. on 80M that would be about 66 ft. but as far as you can
in any event. some claim choke balun at 22' down the feedline works
well Mine is about 30' then a choke balun then about 75' to the shack
and it seem to work for me.

Mid-'80's ICOM R71A for sale. Recently removed from sailboat as I am looking for RX/TX capability and this SSB is RX only. It works. It shows no outward signs of any abuse. It comes with owner's manual and some schematics. No AC power cord.

Since anyone interested in such a machine knows its value, I'll ask that you simply make me an offer that will satisfy both of us.

QRO is fine if you live in a thick rain forest and can't get your antenna up over the treetops, or if you're using Morse or SSB to set a new distance record, but otherwise, otherwise. Before PL tones became SOP my main VHF/UHF problem was pulling up multiple repeaters with anything over 50 watts and even that was too much on some frequencies, so I learned to strictly limit my power output. Nowdays most repeaters have PL tones that prevent unwanted activation BUT using enough power to trigger them with the tone means I'd be interfering with QSOs on them even with the PL off. If I come up with a 100 watt signal, sans PL, but some OM close to the repeater keys it up with a HT, my RF and voice is going to QRM his. Thats why my VHF/UHF amps have gathered dust for over 10 years and my primary VHF/UHF rig is a VX-2R.

2027. Lopp antenna Question-Re-Post

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-18 14:51:38 UTC
From: nospam_deepsea_77@yahoo.com
Message-ID: <41236cc5.1102255@news1.news.adelphia.net>
Source record: 90747

Questions on this antenna:

No takers the first time, so re-post:

==========

http://www.pcug.org.au/~prellis/amateur/space-miser-80m.html

1. Think this will stand 150 watts AM? That 300 ohm twinlead looks a little fragile for a capacitor...

2. How critical is the actual ratio of length to height? Seems to indicate a length of about 23-24 ft (upper end of band), and I only have about a 20 ft run to work with...making the height a bit taller... so the whole thing might come out a bit taller and a bit narrower, once it was hung.

Thanks to the group in advance,

Lin/KJ6EF

I've used bees wax and it has worked fine, though I have no way to
measure losses, if any. You can melt it to get your toroid free if you
need to. I have done this when wanting to put the same balun on
different feedlines.

Hi Lin,

This is one that you could easily model with the free version of EZNEC. It won't answer the robustness of the twin line cap, but presumably the author of this design had already put that to the fire.

As for its description, nothing seems out of the ordinary.

2035. Wizard Radio in Seven Corners, VA, to receive WHFS in Annapolis-followup

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-18 18:47:24 UTC
From: DGoncz@aol.com
Message-ID: <5d8971ea.0408181047.3d836ccb@posting.google.com>
Source record: 90756

Hello, fellow radio amateurs!

I am unlicensed and do not transmit except I send guitar voice mail on the phone and also I send the guitar through FRS for fun.

With twenty feet of twinax from IEC, I am now able to receive WHFS in stereo from Annapolis, MD, here in Seven Corners, VA reliably. We'll see if it works at night.

Both the antenna and 1/8 stereo phone plug terminations need work, but are working.

Could any of you tell me where I can buy some pretinned 1/8 stereo phone plugs with metal sheilded barrels? The ones I buy at Radio Shack don't tin well with rosin flux and a fresh tip, using 60/40 solder. I have to scrape them to bare metal and heat them so much the plastic insulators soften a little. At these frequencies, that matters. Yes, I replaced the polyethylene between the legs with hot melt. Of course I did. But still, see below, there are refinements.

I don't know what engineer at Wizard decided to run their dipole antenna in through a phone jack. Fer cryin' out loud, was it just because the line output is a phone jack and they couldn't spare two cents? What a hassle.

What a nice radio, now it's done. I will get the serial port version soon and have a free slot for a second OEM IBM speakerphone modem. But that's another story.

By using the VU meter on my Cool Edit, I was able to point the antenna. I braced it off the ceiling with a cigarette pack and a strip of double sided foam adhesive tape, then tapped it with a wooden paddle to move it about a degree at a time. It's not an RF meter, but it does get an optimal result. T and I will switch positions next time, so I can interpret the varying audio levels during transmission as indicators of reception quality. Variability was over 30 db. I'll provide a better estimate when we swap positions. I was the one moving the antenna this time.

The transmission line hangs straight from the ceiling to the floor, tensioning the twin leads to form an air spaced graduated line. If you stand too close to it, the signal fades, even though it is sheilded. I guess I need a good ground. This is twin wire in this older apartment, not properly grounded. I can go up then rightwards into the heat pump box and terminate to a ground there. No, not the Freon pipe, there will be a proper ground there and I will find it. I've got the long bit already. Best would be to replace the hard corner on the plaster

wall, burying the ground leading up from the baseboard behind it, or to groove the face of the wall and bury the ground there. Yes, I know that isn't to code.

Anyway, if you know where to buy a good quality, readily tinned phone jack, please let me know. Likewise, if my soldering technique sounds off, please, reply. If you know already through experience that Radio Shack is not the place to go, let me know that and I'll visit Arlington Electronic Wholesalers for a quality product. They are only a bike ride away.

I'll give the details of the terminations later, once, as they are, then again, after I've optimized them. I've got five extra feet of cable so there's room to play with terminations at both ends.

God, I love new, local music.

Yours,

Doug Goncz

Thanks for the reply. I had seen formulas for dipoles using 468/FMhz
and the V's were always 2 to 5% shorter, which would make the V about
16 foot per leg. But I guess that's not taking height and angle into
consideration. I'm learing so guess I have more to do. Thanks again.

Jerry

Hi Jerry,

At best, such formulas are a starting point, and one should always cut the wire LONGER than any solution offers.. This is so that you can trim it to accommodate local variations in geology, topography, interfering trees and houses and the world in general.

Modeling programs attempt to anticipate a myriad of complications, such as your height and angle variables to aid in construction. Also, modeling programs attempt to portray the consequences of building your antenna by providing matching information and launch characteristics so that you can vary elements and observe the impact of your actions before you start building.

This is all relative of course. Your back yard may not conform to the model's expectations, and you would then experience a divergence from your own expectations of performance. However, even in this regard you have a basis of comparison. You can vary the model's settings (generally this reflects a poor choice of ground type or wire size or its insulation) to conform to your reality, and then alter the model to what your desired characteristics and be relatively assured that changing your physical model in a similar manner will result in greater success.

[... snipping all the agreed to parts so far...Sorry, but all the history is
just too much﷒not to mention what follows! ﷒. . . . .]

ALSO, ART. PLEASE do something to make your responses obvious in the body
of text, like line spaces, or lots of asterisks or something so I can find
your responses.

***** maybe like this

Also, you can use a word processor to compose these messages and get the
benefit of a spel chek. Hi hi , I am right now, then Cut & Paste into your
news-reader.

On to the topic﷒

Steve said:

> >So, if we change the velocity direction (to
> > always be tangent to the circle) , but not

> > the magnitude (or speed), then we
> > have acceleration - what we call radial acceleration.

Art:
> Not sure if I follow that.

Steve: I am only describing what it takes to get motion around a circle.
It is basic physics. I'll try saying it several other ways:

The "thing" which represents the acceleration that is causing
the movement in a circle _IS_ a vector pointing toward the center of the
circle. The object is being accelerated toward the center of its orbit.
Its acceleration _IS_ directed at the center.

Another way to say it is; "In order to get the thing to travel
in a circle, you must accelerate it toward the center of said circle and
this acceleration is caused by a constant force toward the center and can be
represented by a vector pointing toward the center.

Good old F = MA is also a vector equation. That is, it can be
used to account for the direction of forces and accelerations. If the force
is in a given direction, then the acceleration is also in that same
direction. (a logical conclusion is that the acceleration is also changing
in order to remain pointing at the center as the thing moves around the
circle)

It appears that you call the acceleration one thing and the
vector another, but they are the same thing, not two different things. So

it appears to me that you are trying to make the vector something else, or
something new to get some new effect. This is where I am confused as to
just what you are thinking is the effect.

[...skipping ahead, some, but basically repeating in new terms ...]

> ART:
> I am saying that energy is inputed to maintain constant speed which can be
> seen as creating a CONSTANT force vector at a tangent

Steve: Yes, (in _uniform_, or constant circular motion) it takes a
constant inward force to get the constant inward acceleration which results
in the constant circular motion. HOWEVER, I have a SERIOUS problem with this
word "CONSTANT" in this context I address below.

Steve: Moving away from the basics of uniform circular motion and on to RF
in a wire.

ART:
> Yes because when the radiator is straight it is phase change that creates
> cyclic current change ala accelleration.

Steve: OK, so we are back to this electron flow in a straight wire
following the sinewave in current, or "cyclic current change ", to use your
terms. Sure.

I don't under your cause and your effect here because I do not
understand what it is that you refer to when you use the words "phase
change".

It is the _generator_ (or transmitter) which is causing the
current and all the acceleration(s)...many per second. The generator
produces EMF or voltages which alternately drive current first one way, then
the other, in this sine wave fashion along the wire. EMF (Electro Motive
Force) is call this because it acts like a force to move electrons (causing
current) in the wire. It is this force which causes the accelerations and
motions.

The generator accelerates the electrons, not what you call "phase change"--I
don't know what this means. There is a change in _current_ over time, but
NOT phase.

Art:

> In the case of a circular radiator I understand that there is no phase
> change a nd the radiation vector is a constant. This may well be the nubb
of the
> misunderstanding.

Steve: I think there is a definite nubb here! You appear to have jumped
to DC away from RF. We should be talking about the SAME type of varying
current, therefore there is still the sinewave form of current flow, the
same accelerations. We do have an added velocity change around the circle,
but we haven't taken away the sinewave of current

Steve: I also think you are wondering if this radial acceleration does
some
> > special radiation that is different from the radiation of the charge
> simply

ART:

> That is correct in that current variation is constant in one case and
cyclic
> in the other

Steve: First, I wouldn't use phrases like "current variation is
constant". Either there is a variation, or it is constant. This phrase
implies that something is varying in a very repeatable or constant manner,
like a sine wave or square wave or triangle wave.

To answer the content of this comment, most emphatically NO! There is
always the cyclic, sinewave variation in current when you bend a current
carrying conductor into a circle. The AC sine wave doesn't go away.

Steve: I skip the area under the curve comment and continue with comments
on your cosine reference.> >

ART:
> Yes I see the phase change as shown by the current curve.

Steve You gotta drop this "phase change" phrase. I think you simply mean
the voltage change over time, meaning the sine wave of current that is a
given in this situation.

ART:
> and in the case of circular motion I do not see a phase change (I cos
phi)

Ahhhh! OK, perhaps this direction will help. Lets talk about your
formula

>>> I COS(phi) which is, of course I*COS(phi).

This formula gives the current at any _instant in time_ when you
plug-in that value of time. However, "phi" is NOT one number. This is
actually I*COS(wt) that's omega times "t". This is the formula, or
mathematical function of the sinewave of an AC signal of constant
frequency just what we are talking about.

This is "I", which is the peak magnitude of the current under
discussion, times the cosine of the angle given by multiplying the frequency
(omega) by the present value of time Which is CONSTANTLY INCREASING as
time progresses! This means that the current is constantly changing. If
you plot these values versus time on a graph, you see our friend the sine
wave and the tops and bottoms are exactly "I" high (away from zero).

Steve:
> > You keep mentioning "constant speed" yet we are talking, I thought,
> > about an antenna with RF current in it.

ART: Yes

STEVE: > If this is the case, there is _NO_
> > constant speed of the current. It is constantly varying in a sine
wave.
> > It has a sinusoidal speed variation and therefore a sinusoidal
> acceleration

> Yes I agree. That would be of the value I cos phi with cos phi providing
the
> sign wave. I believe we are saying the same thing

STEVE:

Then I am unable to understand where you are going. I see nothing new (
in regards to the basic physics above) created by the antenna being in a
circle. We just have AC flowing in a circle.

Some of the problem is your un conventional use of the terminology which
makes the transfer of the underlying concepts & ideas difficult. It is ok
to not be formally schooled in a subject. You can be what we call
"self-educated", but you must learn to use the terminology in he correct
ways (according to the way the vast majority of us use it) or you won't be
able to make yourself understood or understand others. Like I tell my
students, you MUST learn the terminology and use it correctly--- while in
both cases your head may really hurt, there is a world of difference between
a headache and a subdural hematoma!

ART: It may well be a difference of terms applied but I am pleased you
follow
> the main drift of what I was saying so you could be well armed to
> correct me where I was wrong.

Steve:

You go on to describe what seems to be an antenna composed of several large
horizontal, circular, or perhaps better described as helical, elements
stacked one above another, where some are wound in right-hand sense and
others in left-hand sense. I'll not go there because I believe you are
looking for some kind of a new phenomenon which is the result of this
arrangement. This may sound elitist, but I believe you are trying to
discover new physical principles with limited knowledge of the physical
world. It appears to me that your limited knowledge and ability to put
concepts to words leads you to believe there is a magic bullet just waiting
to be stumbled upon and that you can do it.

Antennas, past the simple dipole (although the basics of radiation is a
great source of confusion in itself) get complex really fast. A firm
understanding of how the currents in all parts of an antenna cause remote
fields that superimpose to cause the total, resulting field is critical to
being able to devise new and improved antennas, if they exist.

Go ahead and have fun modeling antennas. See what comes out of various
configurations. I recommend starting out simple to give yourself some

understanding of 'what' causes 'what'. Using this, build a model in your brain (one that suits you) which ALWAYS explains all the observer phenomena as you move along. Your model must NEVER violate any laws of physics or fundamental principles which are known to be true. All this must also make sense or "fit" when viewed with all other fundamental concepts, but understand that much will be mysterious to you without this understanding.

I applaud your desire to learn and experiment, while I am sad that you have insufficient background preventing you from seeing some of the real beauty of the natural phenomena we call electronics.

> My very best regards to you and thanks for hanging in there as opposed to a
> derogatory comment
> Art.

It saddens me when I read some of what is posted. Hams are generally a very friendly lot, but the Internet (UseNet in particular) somehow releases the evil in some. We all have our weaker moments. Some of us are just a lot closer to them than others. All I can do is a Tsk, Tsk and move on.

I must lead my life to a higher standard&#65533; It's a dirty job, but somebody's got to do it.

Some people go to church and then cut you off and swear at you in traffic. I don't do either any more.

Hello,

Dumb question for all of the experts:

In a beam antenna, such as a Yagi, Quad, Hexbeam, Moxon square, etc
what purpose does the REFLECTOR server during RECEIVE???
Does it enhance the received signal any at all, or, in the case of a quad,
are you receiving only as if you only had a vertical loop antenna??

thanks & 73's
Ken

Hi Ken,

Antennas work the same in both directions, so to speak. The reflector
and directors offer the same benefits to both receive and transmit.
In a sense they distort the medium around them to present variations
in phase such that they add/subtract in a convergence with the
"driven" element. They are the optical equivalent of lens elements in
a complex lens which aid in correcting aberrations and
enhancing/increasing magnification.

In isolation, the reflector for a receiver acts as a shield blocking
signals arriving from behind the reflector. The success of that
blocking action is not complete, but through spacing with the driven
element can produce a range of responses which are offset by other
considerations (like matching impedance) varying along with those
changes.

There's a small program named INV_VEE available from website below.

It will tell you immediately all you wish to know about interactions between wire lengths, height above ground, apex-angle between 0 and 180 degrees, wire-size, feeder loss, SWR, radiating efficiency, etc., of any inverted-V at any fequency.

It won't tell you much about its radiation pattern but that's already a simple, well known property of the popular inverted-V. For practical purposes, at ordinary apex angles, it is omni-directional and fairly low-angle as EZNEC is designed to show you.

Download INV_VEE in a few seconds and run immediately. Good DX-ing with it.

Free to USA citizens.

Steve I thank you for your response and I am beginning to see and have
confidence in what I am saying alss I believe I over explained things which
really created problems.
Energy alonf any member travels at the speed of light wether the member or
element is straight or converluted.
In a straight member the current under goes a phase change at all times thus
from one direction the current varies according to I Cos Phi i.e.
accellerating in value and decellerating in value.
When the same electric current follows a coiled load there is no phase
change and the curreny does diminish slightly
due to resistance loss and the effect of inter coil and capacitance w2hich
vastly affects the impedance as the
current moves around the coil..
because there is no phase change and if we are able to remove the rising
inductance and capacitance created by the close proximety of coils we can
then attain a resistive value of impedance or at least progress to that end.
Thus when you travel around a single coil you are not affected by the
inductance and capacitance in a wound coil so the question is how to achieve
this without a closed loop.
What I did before was to use a small number of open coils made from 1/2
corregated copper transmission line and placed them at various heights as
required by my programing where it provided a very large bandwidth.
So what you may ask, what were your measurements!
So I decided to use upto 20 loops attached to a 40 foot
fibreglass tubing tower. This required a program containg
over 400 segments plus 20 variable dimensions to cover the various distance
between loops and where I predecided on the loop diameter. So you can see
that for this many loops in series makes for a very long program
and with the extra checking I must do so that prior trends
are duplicated. All of this isw intended to produce a vertical for a band
below 20 metres where its actual height and signal strength will be proof of
the pudding.
Thanks again for staying with me and for your advice.
I will definitely keep you informed if the results mirror my previous tests.
I have the tower and I have made the loops and just need one more overcheck
on yhis very long program. Somewhere in between I will work on this laptop
so it will provide readable script and also transfer
my computor program.
Very best regards
Art Unwin KB9MZ......XG

I guess I should have said I don't normally use FM or repeaters. Tropo scatter is a fun thing. And I like HF also, but normally run only 100 watts, since it propogates so easily. ;)

A very rare, welcomed, combination of events has occurred.

First we have a sensible, concise, well-presented enquiry about inverted-V's.

And secondly we have a response from Richard (Clark) which combines both his advanced (never doubted) technical knowledge and his ability (but long awaited) to express himself in the logical, unambiguous, easy-to-understand English language.

Makes a change from the deliberately confusing, psychologicially mixed-up stuff we are accustomed to. Keep up the good work.

But may I say I have learned a lot over the years from your own how-not-to-do-it mode of expressing yourself.

Richard, please forgive me for being so forthright in public. I'm on Valencia red this evening. I'm sure you will understand.

Incidentally, I think the English and American languages, after a generation's lapse, are coming back closer together again. You get rid of Bush and we'll get rid of Blair.

Yours, Punchinello, G4FGQ.

>
==========

Receiving and transmitting antennas are reciprocal. They behave identically
in performance and radiation pattern for either direction of transmission.
It's just another law of nature, the word of God, or a scientific dictate
according to your view of the World.

Reg.

Which should be more efficient: Using an ATR-30 to match a 300 ohm load directly through a W2DU type balun, or using the same tuner to match 150 ohms using a CWS Bytemark 2:1 balun? Bandwidth is not a concern.I already have the tuner and baluns. I realize there may be little difference between the two choices, but I will be using the tuner and one of the baluns anyway.

73,
bob

For most part must agree with all, and REMEMBER, that these are NOT totally exact-- for instance- done
same with (YE-GADS!) a 6 meter 7 element yagi, with pretty well known properties, by M-Squared, both in
YO, and in EZNEC-- and the forward gain is more or less identicle, but the F/B is something else! However, didn't
taper the elements (first 18 inchs at a given diameter, rest of el length, a smaller size tubeing-- does this make
EZNEC an error prone program? NO! t'was my fault in NOT takeing the time to input all those extera connections
into the model ! (tho, would be interesting to see it PROPERLY modeled, and admittedly, YO handles this much easier
for a yagi- did the same for a DX engineering, (elements ALL same diameter) and forward gain is about the same
and the f/b is within 5 db (the 7 elM squared is about 15 dB different F/B)
But all in all, best to trust EZNEC-
seems pretty much dead on for most applications. as info-- Jim NN7K And, PS, is nice to see a CIVIL conversation
here! JF

Set up the yagi in YO with the proper taper, and then save the yagi
design with the .ANT extension. This will cause YO to save it as an AO
type file. That should get you a well along the way for your EZNEC entries.

Bob-- Effecient?? That term can apply to the LOSS in your feed line/
VSWR?Frequency!
and, obviously, the POWER HANDLEING capabilities of the tuner/feedline!
But, generally, unless
you are at VHF, with couple hundred feet of feedline (I.E. 10 meters, or
below)! any effeciency
difference will never be HEARD!! the loss diff will probably be less than 1
dB!
My advice? go for it, as long as it is in your tuners power rateing, for hi
Z mismatch!
Jim NN7K

We've had a LOT of fun (& publicity)here in New Zealand over DIY antenna brewed up for 2.4GHz USB WiFi.See => www.usbwifi.orcon.net.nz The parabolic Chinese cookware used gave ~15dB gain at 2.4GHz, but of course any radiation will be concentrated at a parabola's focal point. Aha - could suit "log cabin in the woods " cell phone boosting ? Indeed it does, & 900/1800MHz GSM cell phone reception improvement has also been verified when the phone is cradled at the FP. Naturally you'll find it hard to speak at this position,unless perhaps a Bluetooth headset used, but at least inward calls/text messages can now be received. See => http://www.usbwifi.orcon.net.nz/cellbear.jpg & http://www.usbwifi.orcon.net.nz/wokaxim.jpg

This sure beats constructing Yagis,& 12" woks here in NZ are just ~US$5! Stan (ZL2AJZ)

Hi Stan,

Mine doesn't quite fit a paraboloid. Here's some fun checking the gain:

Gain approx= 10 D(waves)^2

My wok is about 36 cm, or approximately 3 waves. Thus I would expect about a
factor of 90 in gain with 100% aperture efficiency.

You've possibly lost about 2-4 dB. But--you're cookin' anyway:-)

73,
Chip N1IR

2064. Re: Wizard Radio in Seven Corners, VA, to receive WHFS in Annapolis-followup

Message-ID: <20040819075152.19157.00003714@mb-m06.aol.com>
Source record: 90685

Here are some pics of the antenna:

08/19/2004 07:45AM 112,318 CeilingSpacer.JPG
08/19/2004 07:45AM 111,110 HangerAndLead.JPG
08/19/2004 07:45AM 137,884 LeadCloseup.JPG

and links:

ftp://users.aol.com/DGoncz/Antenna/CeilingSpacer.JPG

ftp://users.aol.com/DGoncz/Antenna/HangerAndLead.JPG

ftp://users.aol.com/DGoncz/Antenna/LeadCloseup.JPG

I intend to air-space the twin leads down to above head height, then move the remaining twinax to the hanger, after adding a _little bit_ of weight at the bend to tension the leads. This should form an air spaced graduated impedance "converter" without the need for a minimum loss pad.

If I could just get a more easily solderable stereo phone jack....

Maybe even one rated for RF....

Hi Doug,

Sounds like you need more practice soldering. All this scraping you
describe is unnecessary because you should already have bare metal.

>I don't know what engineer at Wizard decided to run their dipole
>antenna in through a phone jack. Fer cryin' out loud, was it just
>because the line output is a phone jack and they couldn't spare two
>cents? What a hassle.

The jack is not particularly an issue for its use, it is your attempts
to connect the twin lead to it (if that is what you mean by twinax).
You need to go to radio shack and buy a TV-Coax BalUn. You can
recognize it as a small (little finger sized) device that transitions
from twin lead to Coax connections. It usually has a twin lead dangle
with female Coax connector. Then obtain some small diameter Coax (it
doesn't really matter what impedance, so go for esthetics). The small
Coax should more readily adapt to the phono plug and not be so stiff
as to strain it. Choose a long lead of this Coax and attach the phono
plug at one end, and the F connector at the other (make sure to buy
one you can solder to if you are getting smaller diameter cable, and
practice your soldering with the expectation of wasting something
before you succeed).

There is nothing particularly precision about this, so close attention
to spacing, such as you describe it, is not very productive. If what
you describe as twinax is Coaxial cable, you have more issues of
soldering skills and antenna placement (get it outside).

>provide a better estimate when we swap positions. I was the one moving
>the antenna this time.

For the distance between you and the station, try to get the antenna higher (yes I know you are against the ceiling, this too may be an issue). If you can, move it outdoors and UP. Your VU meter is all you need to confirm signal strength (at least to find the signal). To insure you are doing your best move the antenna left-right/up-down to find all 4 points where the signal completely goes away, and then split the difference for a center. From your pictures it looks like you have an outside antenna and not rabbit ears anyway (you need a picture more removed from just looking at wire connections).

> If you
>stand too close to it, the signal fades, even though it is sheilded.

Skip all considerations of ground. Your problem is YOU reflecting signal and acting as a second antenna - another reason to get the antenna outside.

Dear Richard,

You have my thanks for your reply.

>From: Richard Clark kb7qhc@comcast.net

>Sounds like you need more practice soldering. All this scraping you
>describe is unnecessary because you should already have bare metal.

I have 36 years of experience soldering.

Have you tried tinning Radio Shack's 274-284 connector? It acts as if it's made of stainless steel. Maybe a chisel tip would work better.

One problem I am having is all my tools are at my home shop and the antenna and radio are here at my office. Going back and forth confuses me.

>The jack is not particularly an issue for its use

I think there's a reflection at the jack, forming a resonant tank. The frequency depends on the cable length. A little less than 20 feet.

>it is your attempts
>to connect the twin lead to it (if that is what you mean by twinax).

I had used twinlead. I went to twinxial cable, two 20 gage conductors with polyethylene around them, in a polyethylene carrier, with a foil shield and what must be close to 100% overbraid. It is Coleman Cable 99301 20 gage 100 ohm twinaxial type CL2.

>You need to go to radio shack and buy a TV-Coax BalUn.

No, this is a stereo phone plug with balanced signal on tip and ring. I have added ground on the barrel. The original antenna is a 22 gage dipole insulated with polyethylene, not PVC. Each leg is 30 inches long. The pair to the plug is 39 1/2 inches long.

>If what
>you describe as twinax is Coaxial cable, you have more issues of
>soldering skills and antenna placement (get it outside).

The condominium association will not permit an outside antenna.

>For the distance between you and the station, try to get the antenna
>higher (yes I know you are against the ceiling, this too may be an
>issue).

We're on the third floor. I note that if the antenna is allowed to tilt, the signal fades. I have replaced the cigarette pack spacer by a foam block. It's level now. The boom surface is three inches from the ceiling. Should it be farther from the ceiling?

I just filed up a chisel tip.

This morning I lengthened the lead from the antenna to the twinax by stripping more shield, foil, and filler. Now it works very badly. No stereo reception of WHFS. Extending the sheild with foil helped. The legs are 18 inches long.

What I need is:

How long should the legs be at the antenna end?

How long should the filler alone be?

How long should the section with foil over filler be? (Should this foil be tapered?)

How long should the braid be?

How long should the rest of cable, in its natural condition be?

What's a good way to terminate the twinaxial cable to the phone plug?

I have a short connection but no picture.

After I tin the plug, I really don't know how to do this best.

Ok, I've tinned the plug. It was much faster and easier with the chisel tip.

Now what, I wonder?

Yes, Jim-- I agree with you in that the difference will be very
small, and
is more academic than anything. I have the antenna and feedline up and
working (at a portable location), so now I'm just playing with ideas. I want
a simple antenna for a small segment of 75 that will be as efficient as is
practical. I will be operating out of my truck at a power level of no
more than
500 watts, and most of the time will be barefoot. What I'm curious about is
the tradeoff of tuner efficiency between 150 ohms and 300 ohms by using
either a 1:1 balun or 2:1 balun. My guess is that there will be less
loss at
150 ohms with the 2:1 than at 300 ohms with the 1:1 W2DU type balun.
The 300 ohm window line is matched to the antenna, so there is little or no
reflected power at resonance and only 4% reflected at 3.870 and 3.4% at
4.0.
Eznec 4.0 shows that the tuner will see 317 ohms at resonance with a 1:1
balun. The system is working now, and I'm just nitpicking minor details at
this point.

Why would Radio Shack spend more for stainless steel? Who in their
right mind would produce it? I have never had any problems with the
cheapest of materials to wet with solder. You are having some other
difficulty and it may be this wire you are trying to use (ever try
soldering old telephone wire?). Does it wet easily?

>I think there's a reflection at the jack, forming a resonant tank. The

20 feet is not resonant (first resonance that is) at any particular
commercial frequency.

Sleeve.

>The original antenna is a 22 gage dipole insulated
>with polyethylene, not PVC.

Immaterial really.

>Each leg is 30 inches long. The pair to the plug
>is 39 1/2 inches long.

Still rather immaterial. There are optimal lengths, but trivial for
receivers.

>We're on the third floor. I note that if the antenna is allowed to tilt, the
>signal fades.

Indicative of multipath rather than actually pointing at the
transmitter. Your antenna is looking into a soup of direct
transmission waves, and reflections, re-reflections and so on.

Alternatively, you don't have enough signal, and all the tilting,
wiring, jacking, and soldering in the world is not going to make up
for it. Add about 10dB of amplification at the antenna.

>I have replaced the cigarette pack spacer by a foam block. It's
>level now. The boom surface is three inches from the ceiling. Should it be
>farther from the ceiling?

There is nothing good about its close proximity. However, it may be
benign. You should not be as close as the length of any antenna
element from other conductors (you don't know what is in the ceiling
for the thirty odd inches proximity).

>I just filed up a chisel tip.

That is poor practice. You are already melting the connector's
plastic. Solder should flow within seconds at these small dimensions
for even a 30W iron with a pencil tip.

>This morning I lengthened the lead from the antenna to the twinax by stripping
>more shield, foil, and filler. Now it works very badly. No stereo reception of
>WHFS. Extending the sheild with foil helped. The legs are 18 inches long.

Like I said, this is all futile reminiscent of tin foil rabbit ears
aligned with the rising moon and setting Venus. Your signal is
marginal and suffering from multipath to boot.

>What I need is:
>
>How long should the legs be at the antenna end?

Length is not an issue, separation is. Even here it is of no
particular concern. The enforcement of that is dictated by the
mechanical connections at the antenna and the taper to the usual,
conventional twin line has been commonplace for 60 years.

>How long should the filler alone be?
>
>How long should the section with foil over filler be? (Should this foil be
>tapered?)
>

>How long should the braid be?

These are unconventional and cannot be said to be aiding you whatever optimal values may be offered.

>How long should the rest of cable, in its natural condition be?

The only criteria is that it should not be so long as to attenuate the signal through loss. Conventional installations for years went tens of feet to a hundred feet - depending upon signal strength. You don't have signal strength.

>What's a good way to terminate the twinaxial cable to the phone plug?

I seriously doubt you have a female stereo connector to plug into - this too is unconventional. If you do, the sleeve connection was never used in the original configuration (the original antenna only had two leads to begin with by your description).

Twinax (Triax) is not conventional and you give every appearance of either shorting out the antenna, and only picking up opportunistic signal strength; or you have a floating shield that is picking up opportunistic signal strengths and coupling it randomly into the receive signal from the antenna. Either way, there is something definitely fishy about the arrangement. If you want to persist with using twinax, connect the two shields together at both ends (and at the phono end, going to the ring, and the center conductor to the tip), and do not make any sleeve connection at the radio.

>Now what, I wonder?

Buy an amplifier.

So, as an experiment, I entered into Google the callsign my dad
(The First W3DHJ) last held before he became a SK nearly 6 years ago.
He was semi-active on packet radio about 5 years before his death.
But, AFAIK, he was never on the internet.
The only hit I got was deep down in the "available callsigns' lists"
hosted at
http://sattrackhouston.com/vanity.htm

So, even at that, I guess you'd call that a "non-specific hit" -- since
it was not about him, but rather about an amateur callsign he once held.

I neglected to mention that this is an antenna for operating portable. It is an inverted V, 50' in the center, and 20' on the ends. 300 ohm window line (from the Wireman) is delta matched, and is for 75 only. Settings on the tuner (ATR-30) when at antenna resonance are the same as when using a 330 ohm carbon resistor and 359b as a source. Predictions from Eznec 4.0 appear to be very accurate (500 segments).

> really created problems.

Art, [short version: We're going to get nowhere unless we have a common terminology. The words you use clearly do not mean the same thing to you as what most others have come to accept.]

Could you, perhaps, tell me in simple terms, just what it is you hope to accomplish or prove, or achieve with all this? What is your goal? When it is built and working per your ideas, what is this stack of "open loops" going to do, or not do [that other antennas don't do, or do] ???

Long version...
I don't think you over explain, I believe you are using the terminology in unconventional ways and therefore I am unable to understand what the underlying concept is to which you refer. You use "Phase change" in a way that I can not understand.

I am unable to get past what you are trying to say here:

> In a straight member the current under goes a phase change at all times thus
> from one direction the current varies according to I Cos Phi i.e.

[If I understand what you refer to] The proper way to describe this is to say that the "current" goes through an "amplitude" or "magnitude" change (a result of the AC sine wave nature of the generator) That is to say-as we know, the current builds up to a maximum, then falls to zero rapidly, then reversing direction and building to that same magnitude in the opposite direction whereupon it falls back to zero and repeats ad nausium. This, of course, is a standard sine wave of current we also call AC or RF.
The "phase", on the other hand, is a term we use to refer to the _whole cycle_ -- all parts of the cyclic variation we call AC or a sine wave. This _whole thing_ can be compared to another sine wave of the same frequency and we can then talk about the relative phase of one to the other. These two can also be the reative phase of currents in differnt parts of a circuit or different parts of an antenna.

The problem is that if there truly is a "phase change" in a sine wave, there must also be a frequency change for a short time until the phase stops changing and arrives at the new value of phase (relative to whatever we choose to be the reference.

A synonym for phase is "time". The time at which a given part of a wave form occurs detrermines its phase. Teo waves are in phase when they are in "time step" or occur at the same time. When they occur at different times, then they are at different phases.

> accellerating in value and decellerating in value.

They are accelerated at various rates, thus change in velocity (which we equate to current)

It "increases" and "decreases" in value. The change in magnitude is accompanied by the requisite accelerations of the electrons, this is true. [note that "deceleration" is simply another way of stating the mathematically accurate negative acceleration]

Now comes the choker...

> When the same electric current follows a coiled load there is no phase
> change

Here's where I choke! I can not, for the life of me, figure out what you mean by "no phase change".
In commonly accepted terminology this means that the frequency of the signal is constant, and it is as far as I am concerned in the in-coiled, straight wire version as well!.
However, in light of your previous use, which appears to mean that the current is varying, this makes no sense, since the current sinewave is still present.

It doesn't make any sense to continue to discuss trying to remove "rising inductance and capacitance ", your "1/2 corregated copper transmission lines", Why you feel the need to NOT have a closed loop, what an "open loop is", or the rest without a common language which allows you to transfer the concepts you which to present.
Could you, perhaps, tell me in simple terms, just what it is you hope to accomplish or prove, or achieve with all this? What is your goal?

Sorry Art.

2072. Re: Serious radiation questin

Hi Hal
I'LL be happy to explain where I am coming from but this time I will try to explain my thoughts
in a non technical way which may be seen as folksy which may well bring some caustic comments
but I do owe it to all since I asked for help.
First
My aiim is to negate the onslaught of inductance and capacitance to ward off rapid changes in
impedances
Secondly
I want to see what changes occur by using corregated material as radiators compared to smooth surfaces..
Now I will rerlate how my thought processes work even tho they may be totally out of whack
but it will help to explain the terms I use.

If one looks at an A.C. generator it can be seen that the shaft rotates at a constant speed and
it helps to see this by attaching a ball on a string and tieing it to the shaft. The circular motion when looking at the shaft endwise
makes the circular pattern very obvios. If however, you look at the shaft side ways on what you will see is a ball going up and down
either siode of the shaft. If one moves the generator a short distance as the ball takes one revolution
a sinosoidal; trace will be apparent arount the shaft axis which can be interprete by some as showing acceleration and deceleration of current
even tho that hwich generates this trace or graph is rotating at a constant spoeed
(This being important because it may be synonamous to some as compared to the speed of light)
Now let us look at another version of movement in that the generator instead of moving in a linear motion takes on a circular motion
and where the rotary speed of the shaft still revolves at a constant speed.
From this. we can say that the speed of energy along the radiator is still the same as in the first example ,but what is different?
If the generator was moved forward in the fiirst instance there was an equal and opposite reaction force which can be seen
as a cloud of dust as a car accelerates forward. In the second instance the car traveling around a circular course showers dust in a continual
fashon away from the track even though it is proceding at a constant speed.
If we try to generate a graph of current versus time the dust generated on a circular track is a constant i.e. then also the current
level on the graph must also be a constant value.

Now let us look at a current flow on a load on a antenna such as a coil
which is hellicaly wound.
We know that the phase will be constant around the first loop but in this
case we have added inductance and capacitance by virtue
of the close proximity of the next coil and the next coil e.t.c which varies
the impedance along the wire and thus rapidly effects
a movement away from a purely resistive impedance. This lead me into
separating the coils from each other by juxtaposition
so that inductances were not additive (I reversed the coil direction as
well as positioning them apart.)
Since all these coils are connected in series one must hope for a
intercoupling effect will bring the current down on these
vertical portions in the event that radiation from them are of the correct
choice, either additive or detractive.
Thus the project is repeated from what I have done in the past only this
time I am using numourus loops in the event that
resulting antenna height will be eye opening as well as very broad banded.
As a follow up the corregations on the loops will be
removed by laying on the surfaces a flat adhesived back aluminum tape(Ihave
no copper tape) To try and ascertain what changes
occur by having a smooth surface radiator
Well Hal there you have it, possibly to long, possibly everything is wrong
and again possibly hopeless to understand
but it the best I can do
Regards
Art

2073. HP 8405 and negative resistance of antenna?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-19 19:09:02 UTC
From: The other John Smith <jocjo-john@yooha.com>
Message-ID: <iV6Vc.7027$3O3.6810@newsread2.news.pas.earthlink.net>
Source record: 90694

Hi, Gentlemen -

I have an HP 8405A Vector Voltmeter. I have the App Note "Measuring Complex Impedance" by HP (thanks to Wes Stewart). I have made a few measurements following (maybe) the HP paper. I have probably been sloppy with the setup and procedure because I came up with a negative resistance a couple of times.

The HP paper discusses negative resistance but does not mention where one would encounter it. I assume it would normally be associated with active device measurements. Is this true? If I measure a (passive) load and find that the resistance is negative, shouldn't I doubt my setup and/or procedure? Is there any condition where a passive, real-world, network could show a negative resistance?

By the way, I have not gotten a negative resistance reading while using a dual directional coupler. I have gotten the negative resistance reading only when using the power splitter method. So far.

Thanks for any insight on this.

I am planning to construct a vertical dipole array for 20m. The electrical calculations are complete (with help from LB Cebik) and now I'm looking for some advice on the physical construction. I'd like to use Al tubing and find unfortunately that this is difficult to come by locally. I will likely obtain this then from Texas Towers and therefore the tubing lengths will be limited to 6 ft each. They do offer nesting sizes so the real question is what diameter to utilize for the lower most 6 ft segment (dipole being some 34 ft or so). Recalling the approx dimensions of commercial vert antennas I've had in the past leads me to believe that 1.25" or so would be sufficient. Comments/advice ?? I would like to do this without guys if possible and plan on attaching the lower-most segments to 4x4's. Thanks in advance all.

Gary

Chip - "cooking " is right ! We're "reflecting" on a small front screen to enhance illumination in fact. Of course mesh parabolas typically only have 80% of the gain of a solid dish, but extensive field trials have verified ~15dB for the 300mm (12") mesh scoop at 2.4GHz, & ~10dB for a 170mm at the same freq.At say 1800MHz cellular freqs, gain only perhaps 2/3rd this =10dB for 12"?

Ref numerous pix & lab. notes => www.usbwifi.orcon.net.nz to support things

I've used EMT (Electrical Metallic Tubing) also called 'Thinwall conduit'
available from Lowes, etc electrical dept.
another (more expensive) option = copper tubing.
If you have an electrical supply nearby - then Aluminum Counduit may be a
good choice - it comes with threaded couplings.... which you should use
Penetrox on - by the way.
My 2 cents worth =
HEY ! what happened to the "Cents" key there's a "$" key - but no cents.

Gary, I have stopped using aluminum tubes a long time ago preferring
to use alumimum tape on fishing poles and the like
For what you are doing I recommend purchasing fibre glass poles on EBay
which are government surplus. These come in just short of 4 feet
and slide into each other.
They are about 1/8 thick walls and about 2" diameter. You can overtape these
with sticky back aluminum
tape that you can purchase at any hardwaer store. As for guys I always feel
comfortable
when I have those especially for steadying things during construction and
removal.
I think I paid about $40 for mine which was 40foot total length.
(P.S. you can scrape the tape off if you designed it to long!)
Regards
Art

Gary -

Here are some suggestions.

1. Texas Towers is a good known supplier, but you can also get 8 and 12 feet lengths of 6061 Aluminum tubing.

2. I talked to Charles Penninger, KC9DAO (St. Charles, IL) last weekend. He does carry 6061 aluminum tuning in the 8' & 12' lengths and can perform custom machining -- if you require.

His "Clamp-It" series of mast clamps may be of interest for your design.
http://www.penninger.com/prod01.htm

His web site is just being developed
http://www.penninger.com/

3. DX Engineering has a number of appropriate parts (radio support block clamps - up to 2" diameter), depending upon how you wish to construct the verticals or attach them to a wooden 4x4.
http://www.dxengineering.com/default.asp?DeptID=6

4. Array Solutions - 41' monster
http://www.arraysolutions.com/Products/asvd41-fs.htm

5. Cal-AV Labs vertical antennas is an approach to study (full sized 1/4 waves)
http://www.arraysolutions.com/Products/cal-av_vfseries.htm

6. Don't forget a static bleeder choke
http://www.arraysolutions.com/Products/staticsurgecoils.htm

A 20 meter field day antenna

To all: I am a amateur SWL and request your expertise with antennas. I currently own a desktop receiver attached to an indoor active antenna. While this setup works alright, I would prefer to try my luck with a traditional longwire antenna. Can anyone answer the following questions?

1. Is there any real difference in reception quality if a string a longwire through my attic compared to running it from the chimney to a tree?

2. If placed in my attic, do I need to 'slope' it downward through the rafters?

3. My current active antenna is a MFJ 1020B. Is it possible to convert this into a antenna tuner by removing the vertical antenna currently attached to it and running the longwire antenna lead into the 1020B, then running a coaxial connection from the 1020B to the back of the receiver?

Thanks for all your help and I would appreciate any product recommendations.

Source record: 90703

I see from my records that you have EZNEC. Open EZNEC example file
4square.ez, and click Src Dat. You'll see that element 1 has a negative
resistance. In the main EZNEC window, open the File menu, then click
Edit Current Antenna Notes. This contains an explanation of the
phenomenon. It can happen only when there are multiple sources, since
the power to create the negative resistance at one source comes from
power supplied by others. If you use a feed system to distribute power
to various elements from a single source, the resistance at that source
can never be negative.

Active devices can also exhibit a negative resitance, but again, there
has to be some source of power, since a negative resistance sources
power to whatever is connected to it.

Your result could be due to measurement error, erroneous setup or
procedure, or, if you're measuring an antenna, RF on the antenna from
outside sources. The latter makes antenna impedance measurement
difficult without a sharply tuned detector, which the 8405A doesn't have.

I was thinking the neon lamp could display negative resistance at certain
voltage/current ranges. The tunnel diode can also.
Not sure right off it they are active devices or not without looking at some
old information I have.

Okay. I have only the one source, so I should never see a negative
resistance is what I read from your reply.

> Active devices can also exhibit a negative resitance, but again, there

Yes. That's why I made sure I mentioned passive. I meant no active devices.

Error was my assumption as well. Thanks for your input, Roy. I'll take a
look at EZNEC as you suggested.

Hi, Ralph -

Yes, I am familiar with tunnel diodes from way back in the 60's. They were GE devices as I recall. In fact, until about 10 years ago, I had an even older schematic from an EDN magazine article that showed how to connect two NPN transistors together to emulate a tunnel diode. Looked sort of like a bistable connection, as I recall.

Anyway, that's why I limited my statements to passive devices although, as Roy pointed out, I did not state that I had only one source.

Thanks.

To test a device, connect a resistor to its terminals. If the resistor gets warm, you have a negative resistance.

The neon lamp and tunnel diode exhibit a negative *dynamic* resistance. That it, the *slope* of the V/I curve is negative at some parts of the range. They don't exhibit a true negative resistance -- that is, under no conditions will you find the value of V/I to be negative.

> typically only have 80% of the gain of a solid dish,

I would seriously doubt the veracity of this statement and would be gratified to see valid documented evidence of this. If the mesh openings are under 0.1 lambda the mesh will appear solid. The problem may be achieving good surface accuracy with a mesh dish.Those of us using mesh dishes on 1296 MHz EME are seeing excellent efficiencies with mesh surfaces-ultimately limited by the ability to properly illuminate the surface. For EME we tend to underilluminate the surface to take advantage of lower side lobes and less spill over, which means "seeing" less warm earth noise.

We had to stop using 8405s in the field many years ago due to the external RF problem Roy describes. Many of the newer analyzers use synchronous detection which reduces the problem, unless the RF signal level from the antenna exceeds the dynamic range of the instrument. Put a wideband power meter or true RMS RF voltmeter at the measurement terminals and see how much voltage/power is there from your antenna. You may have to wait for a blackout to make measurements if the RF is from sky wave signals. If it is ground wave from MW broadcast stations, move.

Doug,
I too have found that RatShack audio connectors do not take to solder
well. Not always, perhaps a quarter to a third of the ones I've used.
A narrow chisel tip has worked well for me as has going to one of the
diminishing number of electronics supply shops for my parts. However,
I realize not every area has such a place. If you have a Fry's
Electronics store in your area it is worth looking there for both
audio and RF connectors as well as soldering equipment - pick out a
few different tips

Hello all, this is my first time posting to this group. I would like to try 160 meters this winter and was trying to get some ideas on what type of antenna I should use. Let me tell you about my lay out first, My lot is 100ft. wide by 800ft
Deep. Of that I can use about 400 feet of it to hang an antenna. I now have a 136 ft. OCF windom up about 45 feet, and it works great on 80m-40m-20m-17m-12m and 10m. I only us the tuner on my TS-940SAT to tune my OCF windom with no problems. I was thinking about putting up a 160 meter dipole. If I would hang a 160 meter dipole up 136 feet or so of it would run next to the OCF windom that is up now, at least within 50 ft. of it. But I could get the 160 meter dipole up maybe 10 or more feet above the windom. Would this be ok? Are there any other antennas that might do the job? I have alot of trees on my land. Any ideas are welcome. Thanks, Dale

More silly musings:

I read, among other things, that the advice to introduce a coax shield RF choke as lightning protection has been dropped, mostly on the grounds that a choke is an EMP pickup.
Hmmmm... That applies to a helical wound inductor, not an isotropically near-deaf winding like a toroid.
In turn, a single-layer toroid winding would offer a flashover point between the hot and cold ends of the winding.

OTOH if the inductor is made
- with a couple of windings on straight drainpipe
- electrically in series
- axes parallel
- oppositely oriented
- spaced enough to reduce mutual inductance (say, one yard or more),
what you get is high insulation, no flashover point, limited pulse pickup (as long as the distance between the windings is << that the distance between them and the putative pulse source).

Another trick would be to make it a single shielded winding.
(Insert warning about inductively shorted winding here -->)

Yet another would be the SPL, the satanist pentagonal layout. It's like a toroid, cept the winding is split in 5 parts, each in the middle of the 3-foot side of a pentagon. The two ends are kept well apart, of course. A weatherproof chandelier is to be lit in the middle as storms approach.

Sounds like fun.

If I find the inspiration I'll put in a phase canceling split-winding choke.

2099. T2FD: keeping the spreaders in place

On my T2FD I used 1/2" electrical plastic pipe for spreaders.

The wire is rather thick: 4 mm^2 conductor section, stranded,
PVC-insulated.

At the moment, spreaders are tied in place with copper telephone
twisted pair.

I am planning to fill the pipes with urethane foam to keep water - and
especially the bugs - out of them.

Urethane should also bond well with the PVC insulation on wires,
allowing me to remove the ugly twisted pair, but I am not sure.

How do you suggest to keep the spreaders in place?

In the 1920's and 1930's there were scores of people
claiming to "hear radio in [their tooth cavity] fillings".

Today, we have more people in more countries with more tooth fillings
near more (and more powerful) transmitters than ever before, yet
nobody claims to hear radio in their teeth. The focus has shifted to
other, more fashionable sources of radiation, such as cellphones.

It all boils down to whether low-level, non-ionizing radiation has any
effect at the molecular level or not.

Conventional wisdom had it that being that radiation non-ionizing, if
its intensity was short of sufficient for inducing macroscopic
heating, it would not be harmful. On the other hand, heating had long
been tied to cataracts and male sterility, and of course to burns.

In recent years, it was discovered that many birds had the capability
to convert the earth magnetic field into electrochemical nerve
signals. As microscopic magnetic crystals were found in birds' brains
(and later in humans' brains as well), speculation is now focusing on
the possibility that physical effects may have some heretofore
unnnoticed chemical impact too.

Bad statistical manipulation is easy to spot, bad data much less so.
As an RF addict and a statistics aesthete, I hope research will
continue, but I am not terribly concerned.

In the open line I bought, slits are cut in the ends of the plastic tubing.
The wire used is insulated and slightly greater diameter than the slits.
Thus friction holds the wire in place.

Hi Dale - most important is the distances you want to work and your available space.

If you want local groundwave or far DX then go for a top loaded vertical (or tower) with a good ground system (maybe supplemented by a low noise receiving antenna, eg loop or Beverage).

You need the vertical component for groundwave and low angle for DX.

If you want medium distances (100-500km?), then some sort of dipole or endfed would be fine. But this same setup would be lousy for local (little groundwave) or DX (straight up angle of radiation).

An inverted L is a good all-purpose antenna, provide the vertical bit is fairly long.

And me? I'm confined to an indoor magnetic loop for 160m, just 1.4m diameter!

> Remove N O and S P A M imbedded in return address

Hi, George -

Thanks for your comments. But, I don't understand how external RF would
cause the problem for the following reasons:

1. My measurements were at about 460 mHz.

2. The nearest broadcast stations were 10 miles away. One AM station and one
FM station.

3. The Vector Voltmeter showed loss of lock when the signal generator's
signal was attenuated.

4. The Vector Voltmeter is not wideband. Here is what HP says about
bandwidth and sensitivity:

"3-16. Phase and amp1itude measurements can be
made at any frequency between 1 and 1000 MHz. However,
the Vector Voltmeter IS frequency selective and
therefore must be tuned to input signals. Tuning is
semi-automatic with manual coarse tuning and automatic
fine tuning. The automatic function tunes both
c hanne1s simultaneously to the channel A signal.
Thus, channel A signal determines the frequency at
which measurements are made.
3-17. A condition for tuning is that channel A be large
enough to trigger tuning. Minimum required channel
A amplitude is frequency dependent as follows: 1.5 mV
for 1-10 MHz, 300 µV for 10-500 MHz, and 500 µV

for 500-1000 MHz.
3-18. The Vector Voltmeter is a tuned device with a very narrow passband (-1 kHz) at the measurement frequency. Therefore, measurements can be made on complex waveforms, and amplitude-modulated signals as well as sinusoidal signals. Pulse modulated signals, however, cannot be measured as the 8405A cannot tune to an intermitten s.ignal."

The 8405 would be unable to lock onto any frequency below about 200 MHz (IIRC) due to the setting on the coarse frequency control at the time.

I readily accept the fact that my technique was sloppy and my results showed it. I just hope it was not due to an outside source. I can't afford to move.

But, I am new to this. My naive reasoning may be flawed. I would appreciate any further comments on this.

Thanks.

John

> tnx es 73 de n1jpr/i2
> http://filippo.ru.ru

It depends on the "orientation" you desire the parallel wires.
If you wish for them to be vertically aligned, then a small weight (e.g.,
lead fishing weight)
at one end of the spreader helps to keeps the wires aligned.

>through my attic compared to running it from the chimney to a tree?

Some. Depends on frequency and length (comparable to wavelength).
This is not as important as it is in getting away from the house as a
source of noise. If you encounter no noise with an attic antenna,
then you are doing well.

>2. If placed in my attic, do I need to 'slope' it downward through the
>rafters?

No.

Hi Richard,

The manual is vague here. You can try it, certainly, but the
preselector may be overwhelmed by out of band AM signals (recognized
by a strange "deafness" to signals you should get), or it may
oscillate (the manual warns of this). If either occur, time to think
of obtaining or building a simple tuner.

>More silly musings:

Hi OM,

I'll tell ya what.... Instead of musing, or re-inventing the wheel, you already have examples from others who went before you with this identical risk and obviously you think they solved it (or at least they dress like those who could).

Climb to the top of the building (you HAVE done this, haven't you?) and LOOK at those antennas and feed lines already there. Do they have this protection you fantasize about? Do they treat anything as ground? Do their lines tie to it?

Is there any evidence of lightning strikes? After all, according to reports here, the flicker of 100000A will melt unobtainium - is that tower sagging from recent bolts blasted against it? Are there any explosion marks and charring along those lines? Do you notice any heat stress fractures where the tower is mounted?

Look over the side, or visit the sidewalk below. Are their any puddles of slag or molten metal? Or is there any evidence of a fine metal particulate mist deposited along side the building (it will look glittery like Disco Makeup for a drag queen)?

No? Do you think they ignored the problem? (What are the chances anyway?) Do you think you will attract a problem they have never experienced? Ask yourself, what makes your antenna so much more attractive when the Eiffel Tower looms over it.

Well, of course there are the products of that near-nuclear EMP. Look around and see how well the occupants of the building survived this terrible act. Is there a high tenant turnover every season of lightning activity? Have you noticed a lot of hearses in the parking lot on occasion (which begs the question, why weren't you fitted into a box too)? When you took your trash out, were there piles of smoldering phones, computers, TVs, clock radios and Internet toasters filling the bins after a rain? The haphazard, zig-zag AC wiring you describe should guarantee these results to some degree - at least enough to reveal any one of these characteristics of catastrophic results.

Finally, and to answer the question why your antenna, and not the goliath above it; building those pentangle chokes may if fact incur a vengeful bolt delivered directly to you. Who knows, in this modern

age that religious metaphor may be embellished to a nuclear cruise missile to fulfill the prophecy of EMP. (Ah! Images of Monty Python's Holy Hand Grenade come to mind.)

Let us know how it turns out. ;-)

All of the metal in my teeth has been replaced with composites or
capped. This shifts the resonance out of the AM band into the marine
band where there are fewer, less powerful transmitters nearby.

YMMV

I have many amalgam fillings and lived < 1 mile from a 50KW. station on 1160 Kc. (they were sending out kilocycles back then). The only thing that picked up un wanted signals was the house built-in intercom radio. You had WJJD about every 50KC on the dial. Of course a razor blade and a pair of earphones did pretty well too.

The state of Wisconsin has a rather good public radio network (also on the net). Saturday mornings there is a doctor's call-in show. A woman called in claiming that she _heard_ music coming from the mouth of her young son/daughter.
So there are claims...
And BTW. I have been working with RF for the last 30+ years and there are absolutely no side eff...f..f..f..ff..ec...t..t..s.

I have this problem in the VHF band, due to a local broadcaster on 104.1
I use a stub filter, but in your case, at low frequencies, a series resonant
circuit would cut that down nicely.

Hi Dale,

A wok has no focal 'point': it is not a true paraboloid. Its the imperfection
in shape, not mesh:-) Ergo the loss in aperture efficiency.

What we encountered were dynamic range problems. The instrument operates as HP says, but if a strong enough interfering signal appears at an input, it overloads the first(usually) active device, causing various unwanted products to appear in band, and sometimes desensitizing the channel. Urban problem with many other radio services nearby, and it doesn't help to be under the landing path of USAF aircraft with their jammers still active either.

Go to the hobby store and get some thin wall brass tubing just large enough to fit over the conductors. Use about a 2" length on each side, and lots of solder. You will need to provide some mechanical support to prevent flexing at the joints, as there will be tremendous stress risers at the ends of the tubing. Impedance bump should be minimal, as the missing dielectric will be offset by the increased conductor diameter.

Hi George,

I understand the situation you encountered, but as I understand the 'other
John's' situation, he was sufficiently far from strong RF fields such that there
would be no problem with dynamic range. My interest is what the meters showed on
his 8405 that would be recognized as negative resistance.

Have just installed a 135' doublet fed with 450ohm commercial ladderline. The position of the ladder line as it comes alongside the house and into the shack is currently very close to where the electrical service line comes in. Luckily I am not picking up any power line noise but I wonder how critical is it that I try to keep the ladderline away from the house and particularly conductive items? IF it is critial how far should I try to stand it off? Comments appreciated.

Hi Larry
Back in the days of external TV antennas and 300 ohm twin lead,
the usual practice was to twist the line about 1 turn/foot to minimize
interactions with nearby conductors.
Additionally, the distance between the ladder line conductors is a good
measure, keep the line 10 or so, more is better, of that unit away from
other conductors.

For the purposes of radio signals, does the shape need to be a specific
paraboloid? Certainly at optical wavelengths a parabola is needed to
focus light from infinity, so a parabola is needed. But at radio
Frequency wavelengths a true parabola is not likely needed. In fact,
considering the difference between a sphere and a parabols, I would
suspect that anything out there is not a true parabola unless it is
arrived at by chance.

6 inches is what I use for other conductors. But you may not like
RF radiation in your house wiring.

Hi, Walt -

I'm sorry to say that I did not keep the data. Shame on me. But I will keep the data the next time it comes up (if it does) and I will post it here. As I said, I have not had negative resistance show up while using the dual directional coupler, only when using the power splitter and pads. Different math relations were used to calculate the results from the two techniques, so it might very well be that it will never show up again.

Our country property where the measurements were made is about 10 miles east of Sulphur Springs, Texas, and about 80 or so miles from Dallas. There are two radio stations there, one on 1230 kHz (1 kW) and one on 95.9 MHz (6 kW). The nearest microwave tower is about 5 miles west of me and I don't think I'm in the path. There are no hams closer than 8 miles to me.

The more I think about this, the more convinced I become that I flubbed the readings or the calculations. I am learning that you cannot treat 2 meter and 70 cm signals casually. For example, when placing a short on the load

port of the coupler for calibration purposes, I can see the phase changing after the connector has made contact but is still being screwed down.

Thanks for your comments.

John

2132. Antenna Switch

Newsgroup: rec.radio.amateur.antenna

Source record: 90654

There is a figure (from ARRL Antenna Book, 20th, Chap. 3, Figure 5, page 3-4) shows the ground current, I-H, induced by the magnetic field, H-phi.

I think there is something wrong with this diagram.

Should not I-H be perpendicular to the plane of H-phi?

Not sure it really makes a difference. Just bothers me either that a) I do not understand or b) it does not agree with the physics book I am looking at. In the latter, induced EMF acts perpendicular to the plane of the magnetic field.

Sorry, tried to attach the figure, but posting rules would not accept.

Hi MIke,
I am not certain I understand your answer- or Chip's.
The original poster made the statement that mesh parabolas are only 80% as

efficient as a solid parabola. That was what I was answering.

I can tell you that my 14' 1296 dish is within 5mm of being a true parabola- this is well within the 0.1 lambda RMS error.

For my purposes- EME- an imperfect parabola (this includes sperical surfaces) would lead to not only a degradation in gain, but much higher sidelobes and therefore worse G/T. It is not a difficult exercise to measure Tsys and therefore know just how well your dish is playing.
Spherical antennas certainly have their place- particularly when the surface is fixed and the beam is then steered by moving the feedhorn- i.e. Arecibo. But from memory, they take 2nd place to the parabola when one considers dB/reflector area

Well, I haven't found one I like, but I can dis-reccomend MFJ.
I've had a couple of theirs, where the connectors FELL OFF.
They are just pressed in.

What bands is this for? The answer for 440 will be different than for 160.

William

I have recently made some pretty good "coax" switches for low power VHF
using TO5 relays. I have also made some decent toggle switchs for 2 meters
with miniature microswitches.

If you have interest in building your own, E-mail me for pictures.

Jerry

Hi John,

I believe I said earlier that the distance to any probable source of interference to your 8405 is sufficient to exclude any interference.

Is it possible to recall what you were measuring, and what the setup was when yo;u obtained the negative resistance indications, such that you could repeat it just to humor me?

And concerning the phase change when screwing down the short, it's possible there's contamination in the screw threads, either on the short or on the connector on the coupler. On the other hand, at UHF the phase can change slightly between having the short placed on the coupler before tightening down vs being completely tightened down.

I use an HP 778D coupler with N connectors, but I normally use a BNC short on an adapter when establishing a phase and magnitude reference. When using sufficient padding between the sig gen and the coupler I find no difference in magnitude of the reflection between the short or open reference.

I'm curious concerning what coupler and sig gen you use. My gens are all HP, the 606A, 608E, and 612.

Message-ID: <cg6h98bvp1@hercules.btinternet.com>
Source record: 90659

Crudely, the lobes in the radiation patterns of the antennas you mention, inevitably distorted by the local environment, are so broad they can be considered largely omni-directional, except that purely vertical antennas always have a vertical null and horizontal antennas don't radiate quite so well in line with the wire as they do broadside to the wire.

The type of local ground also has a disturbing effect. As people seldom know what type of soil they have it's somewhat statistically unpredictable. Which all adds to the fun.

The term "radiation angle" doesn't really apply, its a misnomer, until you have a high, multi-element, directional beam antenna which EZNEC (a computer program) can get its teeth into.

By radiation angles, I have read that a 5/8 has about 15 degree)so good for DXing), and a quarter wave about 25 degress, but I am not sure if that is correct.

What roughly is the angle that a dipole radiates?

It also works nearly as well at 14 degrees or 16 degrees. And of
course only slightly worse at 13 degrees or 17 degrees (you couldn't
tell the difference at, say, 12 degrees or 18 degrees). And at 10
degrees or 20 degrees its not too shabby either, and probably as good
as 45 degrees (but maybe not, hard to tell).

> and a quarter wave about 25 degress, but I am not sure if that is

About, or perhaps it is 28 degrees or 15 degrees.
>
>What roughly is the angle that a dipole radiates?

Most of them. Actually it works best straight up into the clouds, but
that doesn't mean it is worse than a vertical at 20 degrees. Funny
about these things.... Which is better: ski boots or an ottoman?

Hi Richard,

It is all a continuum where eventually in comparison to the best
angle, some angles are obviously worse. If you are going to name one
angle (and it is done quite frequently here) you have to keep in mind
that this in no way defines an antenna rigorously. It is more a
shorthand.

I vote for Cecil's solution.
you can determine the gauge of the wire in the LL with a wire-stripper or
gauge
then at Lowes or Home Depot - electrical dept pick up a pkg of un-insulated
butt splice connectors for that guage wire.
Then solder it.
OOPs - don't forget the heat shrink before the solder. (or good tape-if you
need it)

These are quite irrelevant questions, unless you specify the height of
the antenna (in wavelengths) and the characteristics of the ground
(mainly conductivity) at the frequency of interest.

For instance a horizontal dipole more than 10 wavelengths above ground
would have quite omnidirectional pattern in the vertical pattern, but
nulls in the direction of the elements. Of course, this can be a bit
hard to implement on 135 kHz, but not a real problem on 1,3 GHz :-)

Richard, you gotta pay closer attention to what the doc is doing inside your mouth!

Caps have a ceramic layer atop a metal (titanium?) mandrel. And even more fun is that there's a rather large and long stainless steel post that was drilled down to nearly the end of the root of that tooth. After the post is cemented into the base of the tooth, the cap is cemented onto the post. The post might be 5/8" long, and the cap sits on the post separated by a dielectric adhesive.

Although the nerve was "killed" at the point it enters the root of the tooth, the rest of the nerve bundle really isn't that far from the end of the stainless steel post. Sounds like an interesting collection of resonant structures, lossy dielectrics, conductive fluids and potential diodes; all located quite near to your nervous system.

Any of our EZNEC gurus care to model that structure?

Source record: 90666

Let's try to summarise, and sort out some of the confusion:

* As Dale says, a mesh reflector is almost as efficient as a solid surface of the same shape, even for hole sizes as large as 0.1wl.

* That was a side-track anyway, since the OP doesn't have a mesh wok.

* Any vaguely bowl-shaped reflector - including a wok - will make a big improvement in cellphone performance, if you locate the cellphone at the best possible place, line the whole thing up correctly, and manage to keep your head out of the way.

* A paraboloid is the best shape for a reflector, because only a paraboloid can focus all the incoming rays to a single point; and all the incoming energy from a plane wavefront will arrive in-phase at the focal point. This applies equally to light and radio waves. Optical ray-tracing theory breaks down if the reflector is only a few wavelengths in diameter, but a paraboloid is still the best practical shape to aim for.

As Dale says, Arecibo uses a spherical reflector to allow a few degrees of beam steering by pointing the feed antenna at different areas of the dish. However, this is a very special case: the only practical way to achieve a 1000ft dish was to build it immovably on the ground, so the designers then had to find some other way to steer the beam, by moving the feed antenna at the focus. In this one special case, the optimum shape for the reflector is not a paraboloid but a sphere (because the geometry of a sphere is the same in any direction, as seem from the feedpoint at the centre).

The problem of course is that a sphere doesn't *have* a focal point - it has a smeared-out focal line with phase variations along it. For many years, long slotted-waveguide feeds were used to collect the available energy from along this focal line, and to compensate for the phase variations. By doing this, the Arecibo designers were able to achieve similar efficiencies to a paraboloid of the same size, and with some degree of steerability too. The limitation was that a different feed was required for every frequency of operation, and this obviously restricted the range of research.

With computer-aided design replacing 1950s slide-rules, Arecibo now has a sub-reflector system of a very cunning shape that compensates for the phase variations. Being a reflector it is not frequency-sensitive, and it brings everything into focus at a conventional single-point feedhorn which can be changed in relative comfort - that is, if anyone can feel comfortable suspended out on cables, 500ft in mid-air...

Because Puerto Rico is quite close to the Equator, the Moon passes overhead from time to time, and this allowed the Arecibo observatory to do pioneering work on radar mapping of the Moon's surface. It also turned out that the old 400MHz line feed would work reasonably well on 432MHz, and back in the old days there were occasional empty time-slots when the dish would appear on EME. Sometime in the mid-1980s I had the good fortune to work KP4I on what seems to have been the last opportunity. He was LOUD.

(That's an outsider's view of Arecibo. Chip, please correct any inaccuracies :-)

It's probably K7NV's program, that Torsten mentioned.

You can buy it from K7NV's website (see Torsten's posting) but Texas Towers obviously can't copy it to you.

Basically correct. Although the tracking is better than just a few degrees:-)

Arecibo was initially designed to be a surveillance instrument, passively listening to Soviet communications through inadvertant moonbounce. It also was designed, initially, as an ionospheric heating facility.

Through the huge luck of its overengineering, it was found to be able to track quite accurately, and the feeds and carriage houses were designed to accommodate a greater tracking range.

Today the site no longer has chicken wire (and hasn't for 30 years); and the feeds are Gregorians that accommodate very large bandwidths and spectral ranges. Most of the recent upgrades were funded by the NSF, and also the Seti Institute.

No; but optimum aperture efficiency is attained with a point feed, as you get with a true paraboloid. Spheres work too--if you can make a good line feed.

If you are willing to throw a few dB away, and don't care about the sidelobes and shape of the main beam to any great degree, then all kinds of imperfections from paraboloids work well.

Of course, a pringle can also works at 2.4...so there are many options.

The wok's inefficiencies stem from the fact that it is not a true paraboloid.

If you can find one on EBAY or some trading page look for a Daiwa CS-401.
This would handle 4 antennas from 0-1300 MHz.

No, I'm afraid not. I made so many measurements that weekend that it sort of
turned my brain to mush. I will set up the apparatus as I did before and
repeat some experiments. I like to be humored, too.

> And concerning the phase change when screwing down the short, it's

down
> vs being completely tightened down.

The phase change is not a problem, just an observation. After thinking about it, it makes perfect sense. It was due to the shortening of the path as the shorted connector was screwed on. The change was not large, maybe a degree or two. It just surprised me that the setup was that sensitive.

> I use an HP 778D coupler with N connectors, but I normally use a BNC short on an

I use a 11570A kit which includes a power splitter, two probe Ts, two terminators and a short. I also add two attenuators per the HP application note. All are type N connectors.

> I'm curious concerning what coupler and sig gen you use. My gens are all HP, the
> 606A, 608E, and 612.

Recently I have replaced the splitter and attenuators with a Narda dual directional coupler. It is with this setup that I seem to be moderately successful. My generator is an HP 3200B VHF Oscillator.

I have been running a Butternut HF9V. I recently retuned it after adding the 160 meter mod, and obtained the same results I did when I first installed it. Basically it appears to be a couple of feet short on 10 meters with minimum SWR at 28.9 MHz and long on 17 meters with SWR not falling below 2.8. I am considering buying a 72" 3/8" tube to extend it for 10 meters, but I'm stumped on 17 meters. Has anyone encountered this and found a fix? I have a good ground system with plenty of 30' radials, and the antenna works very well, but I would like to get the SWR down.

Hi Ed,

I know the dentistry business quite intimately. I help a buddy out
with new dentistry technologies. What you describe are rather old
techniques. My dentist built up a cap in the office on an NC machine
in 15 minutes to replace one that had been built without any coloring
(it was as white as chalk). I've only had one root canal after the
dentist got tired of waiting for years to fix the abscess (never
bothered me as much as it did him). Even then, the cap required no
post, he filled the excavation in much the same way as any prepped
cavity and capped it off.

No metal involved, much to the loss of another buddy who has a
patented technique in gold based construction. All the work I am
aware of is now done by casts. By the way, the profit margin is HUGE
for the dentist. He easily pays only $100 for the cap from the
laboratory. I can only hazard a guess to what you pay the dentist
(me, about $600).

> Climb to the top of the building (you HAVE done this, haven't you?)

The top of my condo became very popular after I taught local kids how to pick the locks many years ago, a long time befor I got my own keys. Problem was, they would not limit themselves to our own condo roof. Now the place looks like a WW1 front line, as other condos erected barbed wire everywhere to keep them out. Luckily they can't be seen from the street level...

> and LOOK at those antennas and feed lines already there. Do they have
> this protection you fantasize about? Do they treat anything as
> ground? Do their lines tie to it?

The other ham has a mess of some 20 or so lines, including meteosat x 2, sat-tv x 3, HF wire, HF beam, HF vertical, 2m GP, 2m collinear, 2m yagi, 70cm 2 elements x 16 array, 23 cm dish, VHF discone, weather station, 70 cm moonbounce, plus controls for rotor and azimut mount for the dish. All bonded in several places, and to the lattice tower as well. Plus the guy has a ground from shack on down.

My obvious wish is that any rogue moving charge will prefer his invitation to mine.

> molten [...] unobtainium

AFAIK, properly grounded gear rarely melts, although you tend to get some burn marks where the plasma kissed the metal.

I have climbed as far as about 5 feet above the rotor, i.e. some 30+ feet from the roof and about 140 ft above street level. Any higher would be unwise without a harness (I do not intend to emulate Col. Armstrong, esp. with no chick looking on, although I did drag a few up to the roof). No burn marks up to that height. The unobtainum ingots that lie neatly stacked on the roof look pristine.

> is there any evidence of a fine
> metal particulate mist deposited along side the building (it will look

We do get a lot of that, but it must come from other local sources. Probably drag queens.

> Ask yourself, what makes your antenna so much more
> attractive when the Eiffel Tower looms over it.

Intrinsic beauty?

> hearses in the parking lot

Right, thinking of my numerous pacemaker-equipped neighbors you must be right. They do not fall like flies in an electrical storm.

People killed by lighting in this area tend to be caught by exploding trees in parks. In the last serious case (2 dead, I think + several hurt, about a years ago) one lady's arm was was temporarily paralyzed by the EMP she caught from an umbrella she was holding about 50 ft from the tree that got hit. Those closer to the hit were hurt mechanically, not electrically.

It was really bad luck. It had just started raining, and it was the very first bolt, while they were all leaving the park for a nearby cafe' - they were not braving the storm right under the trees.

> building those pentangle chokes may if fact incur a
> vengeful bolt delivered directly to you.

Plus, any "pentagon" could also get the local jihadis all worked up.

Hmmm, should I get some local priest / imam to come over and bless the hell out of it? A friend of mine did that to all his motorbikes, and they did work more reliably than mine. Now that I think of it, some local catholic priest indeed comes over for a round of apartment-by-apartment blessing once a year, and I always opted out. There must some neighborhood aura of blessedness that got layered on year after year.

> Who knows, in this modern
> age that religious metaphor may be embellished to a nuclear cruise
> missile to fulfill the prophecy of EMP. (Ah! Images of Monty
> Python's Holy Hand Grenade come to mind.)

Pass the Lord and praise the Ammunition!

> Let us know how it turns out. ;-)

It may take a while, esp. as I have to reuse (steal) someone else's abandoned & forgotten flue line to bring the coax to my place.

A former underground garage & repair shop was turned into an unheated undergroud parking facility. They just ripped out the furnace (which for many years had provided me with an excellent local ground, btw!, although they never noticed).

Now I have to drill a hole in a little known structure to access the chimney up on top. A straight 110ft drop! I hope I won't hit asbestos, which is a definite possibility.

When the wire is up, I'll post some pix, I promise!

73 & thanks

Thank you!

My antenna is already build and strung up to stretch before I lock everything in place. The holes on the pipes are slightly too large to provide reliable friction.

I also got email advice (thank you Kees!) to use tie wraps around the wire but _inside_ the pipes. I'll use a couple of rounds of copper telephone twisted pair for that. Twisted pair is an interesting material.

I am testing polyurethane foam with the electrical pipes I used, which are made of some unknown polymer.

If the foam bonds OK, I will inject it, then stick a ball of crumpled alufoil into each end of a pipe, and perhaps dab on another bit of UV resistant glue to block the foil balls in place.

To be more exact, a linear (1/2-wave) dipole produces maximum radiation at all angles perpendicular to its center.

But as suggested by the quote above, radiation from the driven element along with the distance, geometry, and electrical characteristics of nearby conductors (including the earth) will determine the final pattern of the radiated signal.

Well, I'm an old guy! I grew up being conditioned to having carries drilled
and filled. (Never did the orthodontia route though.) I then graduated to
the next life-phase, wher the carries became multi-surfaced. That morphed
into putting on caps. And then the cap jobs moved onto crown jobs. Now I've
got myself my first bridge; hey, I finally own a bridge!

Yeah, crowns are about $600 in Southern California too. Been a while since I
bought one, but I did know about the mark-up. Unfortunately, do-it-yourself
dentistry is quite difficult. I find it interesting that many local dentists
are still one-man shops, while individual practitioner physicians are almost

extinct. I had talked with my dentist about advanced lab techniques like you described; but she got a misty look in her eyes as she described the financial aspects.

Anyway, as it is now, I've got enough metal bits in my mouth that I could probably qualify as a diplexer on some band.

2164. Preferred antenna location

Other than locating an antenna as high as posible and in open space, are there "sweet spots" that behave like funnels for radio waves? By moving a portable receiver around to find the strongest signal, I have noticed that certain locations (I'm talking feet and yards, not miles) produce much more signal strength than others. Of course, I also end up moving the antenna angle too which may be responsible for this behavior. Just wondering if this effect is worth considering when installing an antenna. Or am I just finding the strongest lobe of the antenna pattern?

Hi Ron,

There is merit in doing a site survey, as this would be called.
However, if you are doing this in the VHF/UHF regions, you may wish to
consider that you are part of the optimization by being in the region
of this best signal determination. If you plant a permanent fixture
on this basis, you might want to set up your easy chair nearby to
maintain the optimization.

Okay, I just found a tiny note on a piece of paper which says:

"B1/A1 = .90 at 180 degrees reference (shorted)"

and

"16 and 1/2 inches of RG58A (shorted) gives B2=0.74, A2=0.81, at -110
degrees"

This works out to -0.56 - 35i. Unfortunately, my note does not indicate the
nature of the load.

It looks like the real part goes negative if A1B2/A2B1 > 1. Yes, I think I
see it now. If the reflection coefficient is greater than one, that
indicates more is being reflected than is being supplied -- meaning I have a
source at the supposedly shorted end of the coax. Ah ha! I am now very
confident that I either misread the instruments or misadjusted something.

Anyway, I think I have the answer I was seeking. Except under extraordinary
circumstances, I should never get a negative real part answer.

My thanks to the contributors of this thread. It sure helps to have others
to talk things over with.

When used in an antenna coils have approximately the current distibution characteristics as the part of the antenna they are substituting for. Yuri has an excellent article on this and there has been much discussion about his on the NG. However taken this in the context of the rest of what you have said during this string I dont think this is what yiu are looking for. What you are looking for does not exist.

Al and emt will bend in the first good wind. I have used top rail for chain
link fences with good success. Sections are made to fit together and can be
drilled and pinned together with a bolt.

Tom must be doing something right - he's the only US station I've ever
worked on 160m (with 5 watts QRP & a very modest end-fed wire by the way).

Source record: 90597

John, negative resistance is indicated when the magnitude of the reflection
coefficient is greater than one.
The solution of the impedance equation for rho > 1 yields negative values of
resistance. This lends a lot
of insight into possible causes:

The calibration for open or short is slightly lossy. If a measured load
has a little more reflection than the
calibration loads, it would indicate as negative resistance.

Numerical errors creep into the results. The Smith chart is extremely
sensitive around the periphery.
A few tenths of a dB. result in large movements at the edge of the chart.
Thus, small calibration or
computational errors can result in crossing over the rho=1 circle.

And, as mentioned, detection of external RF fields increasing the output
of the reflection detector
past the calibration value can result in a measured value for rho > 1.

Well, John, there's nothing wrong with your head, except perhaps you're not
really acquainted with the characteristics of shorted RG58's. RG58's are notable
for their storage of heat. After they are energized, and the souce disconnected,
then as the coax cools down and the heat is radiated, a new emf is generated
causing current to flow in the reverse direction. The coax is now a new source
and the power you measured with the 8405 is indicated as negative resistance.

Walt

PS--I once thought I'd become a standup comedian, but the competition was too
great.

Was the RG58 vertical at the time? If you have the shorted up when
vertical, the charge gets pulled back down, causing partial, or during
times of gravitational anamolies, more than complete, cancelation of the
forward looking, i.e "liberal", current, which we all know causes Pointy
Vector to swerve to the right. If you hang the shorted end down, the
reverse occurs, causing more current, or "conservative" current, and
swings the Pointy Vector to the left.

One controversial way to deal with this, is to spin the shorted section
in the horizontal plane, and then we seem to get charge flowing with no
real direction calling itself - "Nader".

Some 35-40 years ago there was an "El Toro" (if memory serves correct, by one of the
major 3 antenna companies, cant remember if was a dipole, or tuned wire sloper
configureation, but was constructed from (think) 450 ohm ladder line, and couple of traps
and good for the low bands. the traps were places on one side of the ladder line, at
strategic locations, to resonate this for (think 80-40-20, and maybe 15-10) Kinda flimsy,
but where not much inclimate wx, seemed to work. Question 1) -- Who made it ?
Question 2), anyone still got manual for it?? (think maybe mosely, or hygain, but then
as stated, long time ago! Mught use coax for cap for it, and coil-- just curious-
Jim NN7K (mail to nn7kexk7zfg@sbc(nospam)global.net (remove the (nospam).

Hi Phil

My antenna tuned perfectly until I added the 160 coil, then I had to retune the whole thing and had lots of woes until I finally found that sweet spot on each band where the SWR was down where it belonged.

It has been a long while and I don't remember, but I did have to make a NEW feed coil in place of that enameled wire one that was more than twice as many turns, same diameter, before anything came close to tuning up right. I used the same gauge wire as the original, just made it with twice as many turns, spacing was closer also. I did find it's best to leave this new coil on a tube because it gets bumped easily. What I did was cut the bottom out of a plastic cylinder about 14 inches in diameter and placed that around the antenna base. A little round-up inside the container from time to time and a box of salt kept the weeds out.

Thanks Gary, I initially tried tuning with the original coil in place and received a 5-1-9 report from 122 miles away. The lower three bands tuned well, but I figured I must be passing 160 right into the ground system. I totally removed the enameled coil and only 80 would not come below 1.7. 40 and 160 matched very well, so I think I can get by with that. Leaving the coil off has resulted in 5-9-9's from everyone I called so far on 160, so perhaps I was right about radiating into the ground.So far, it seems to be doing a great job.

The problem with 10 and 17 meters has been with me since the antenna was new and before I put the 160 kit on it. I have had more pressing issues and had forgotten about it until I retuned the antenna after adding the 160 coil. I have heard other comments made about not getting a good match on 17 meters.

I was hoping someone out here had found a simple fix because the antenna works so well as is that I can't see putting a lot of effort into fixing something so minor.

73,

Phil - N1KI

A quick Google.com search brought these references:

From: Fred Hopengarten" K1VR Mon Jun 13 01:35:32 1994
Subject: El Toro antenna

I used an El Toro antenna for Phone and CW SS as an undergraduate at Colby
College, Waterville, ME, in, I think,
1966. I erected it at two different locations: at the Outing Club Lodge by
BIG lake, and at the blockhouse for
spotters and broadcasters 50 feet above Colby's football field. Colby,
which plays the likes of Williams, Bowdoin,
Middlebury, and so forth, has a football program smaller than most Texas
high schools.

The rig for the contest was an NCX-3 (for you newcomers, a transceiver for
80-40-20 only, ssb and CW --
but CW had no offset and no RIT; but, unlike some other SSB transceivers at
the time, it was stable). I think I won one
of the weekends for Maine, but my conclusion, based on performance that
weekend and the context of other

experiments, was that the El Toro sucked wind. I think I only made about 250 QSO's in 25 hours. Everyone who worked
me that weekend (I was then W1NJL) is to be congratulated. I would say that the signal was equivalent to a bad
experience with an eight foot whip.

If I could relive those two weekends, I'd erect an 80 meter dipole sloping SW, fed with 300 ohm line, into an
antenna tuner (a dipole on 80 and two half waves in phase on 40); and a dipole on 20 (down just 7 dB from a 3 el. Yagi).

Never underestimate the efficiency of a dipole -- just put it up as high as possible.

Fred Hopengarten K1VR
Six Willarch Road * Lincoln, MA 01773-5105
****

In early 1964, Dave Hollander (now N7RK) operated WN6IWX in Tustin, CA. His Hallicrafters "pair" includes an HT-40 transmitter (left) and an SX-115 receiver. His antenna was a Mosley NC-3 "El Toro," and the station was good for 44 states and 10 countries before Dave upgraded to WB6NRK. His Dad, now N6UC, worked for Hallicrafters in Santa Ana, CA.

****
From: Randy A Thompson, K5ZD Sat Jun 11 03:38:59 1994
Subject: Antenna Question

In June 94 CQ Magazine, World of Ideas column by K4TWJ, there is an interesting antenna given the name "El Toro."

It is basically a 1/4-wave of 450 ohm open wire fed against ground.

K4TWJ writes about this antenna:

"Rather than using a single wire "worked against ground" (like a 1/4 wave vertical), it is made of ladder line with ground connected to one conductor. This simple step raises the antenna's signal radiation efficiency from 20 to 60 percent."

I use wire nuts for all mechanical/electrical connections on my wire antennas and ladderlines. Works great and easily removed or changed as needed.

WHFS in stereo at 3 AM.

I note the plug has to be in just more than half way, not all the way for best results. Maybe I should be using a balun, coax, and a phone jack adapter as suggested.

But the original antenna was a dipole. So what did they do, ground one leg? I have checked and the sleeve/barrel at the computer is grounded. I'll pull the board and have another look at the traces. I'm sure tip and ring are balanced but we'll just have a look under the hood....

The flat chisel tip did a much better job of transferring heat to the connector lug and hardly any plastic melted this time. The lug heated quickly and the tip drew a film of solder over it. My apprenticeship ended in 1986.

I filled the space with hot melt, and applied a little over the connection, then taped it, drew over the braid, and whipped the braid down over the end, with the ends of the braid falling neatly into the groove between the threads and the flange. Then I lacquered the whipping with nail polish. I'll heat shrink over it some day.

The boom and therefore the reflector elements are grounded, as they normally would be. I don't know if this does anything. They are grounded from the sheild through a clip lead to a bracket supporting a reflector element.

No active amplification is used.

It works just great. No rabbit ears, no aluminum foil, and it picks up pointed due east as it should. All 10 FM stations on my dial read the same on the VU meter, all are in stereo, and there is very little noise or interference.

Just one thing. There's a cable dangling from the middle of the ceiling.

For now, primary Teri can live with this. We will be sharing this whole space soon. Right now I am renting 26 square feet of office space and paying towards the cable modem and fax line.

Jim -

It depends upon which "El Toro" is being referenced. One was a Mosley beam,
the other 2 different wire antennas.

Sounds like the "El Toro" name has been reused over the years for different
antenna designs.

I don't agree. A 20M yagi half-element is around 17 feet long, a
self-supporting 20M vertical is around 34 feet tall. In your context
he needs to look at the taper schedule for a 40M yagi to get the
drift. The stress in a fixed end cantilever beam like a vertical
antenna goes up as the square of length (stress is proportional to
WL^^2 where W is the wind load). Without actually running the stress
analysis I suspect he'll need a base tube which is around 2.000"
diameter, maybe even 2.500" diameter x 0.058 wall 6061T6 aluminum.

>>>>just deal with him direct?
>>>>73,
>>>>Tom Donaly KA6RUH
>>
>>

I had my share of dealing with Tom direct and pointing out wrong information that he was spreading on the waves of Internet. For that I was attacked by him and called "pathological scientist" rather than engaging in reasoning and discussions. When I tried to defend the truth and reality on the reflectors, I would be unsubscribed by Herr Administrator and Tom was given last word, "proving" he is "right". To those reflectors I never came back and one of them is TopBand. This is #7 gross misstatement from Tom that I am pointing out. I mentioned it here for the benefit of those who care. If anyone wants to worship W8JI and his "pontifical" statements that are sometimes wrong, be my guest.

>> Tom must be doing something right - he's the only US station I've ever
>> worked on 160m (with 5 watts QRP & a very modest end-fed wire by the way).
>>
>> 73, Peter VK3YE http://www.qsl.net/vk3ye

..and that proves that everything Tom says is right?

People can be wrong, and usually appreciate if they are corrected or shown better way. W8JI seems to be "absolutely right" even when he is wrong. He would first ridicule the one who tries to correct his misconceptions. Then if argument ensues and he realizes and is convinced that he was wrong, he would not admit it, but goes quiet for a while and later emerges as a "guru" on the subject pretending it was all his invention. He is doing some things right, but he has this attitude that does not reflect well on hams and it is not manly to attack someone for bringing up correction, and then making it his own "invention", not giving credit where is due. That is called plagiarism.
So, I brought this up for those who care about reality, and I am taking advantage for ability to post here, where reflector Gestapo will not silence me. Tom is hanging around reflectors where he is protected by administrators, when he encounters knowledgeable opposition to some of his fallacies, he can't take the heat, will not admit being wrong and goes and thrives behind reflector Gestapo. I am not looking for fights, I am trying to point out when I see something posted publicly wrong.

If anyone cares to discuss the subject, or explain how the conductor laid on the ground can lose its conductivity, bring it on. I can't figure out how this could happen and I would enjoy being enlightened.

2196. G5RV vs. G5RV Jr.

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-22 15:25:36 UTC
From: Jim Leder <k8cxm@hotmail.com>
Message-ID: <LV2Wc.48074$n7.108@fe37.usenetserver.com>
Source record: 90617

I can read all kinds of info about the 'full sized' G5RV, but I have yet to find any detailed performance info on the G5RV Jr.

Like:
- The original G5RV was designed mainly for 20 meters, with acceptable performance on 80/40 and if you are lucky maybe 17. What might be the optimum band for the Jr., if it has one?
- I've seen EZNEC outputs demonstrating the gain and the lobes the regular G5RV generates, but never with the Jr. I suppose I could attempt to model it, but my skill with EZNEC is limited. Has anyone successfully modeled a Jr? What's it look like?
- Do any GOOD EZNEC input files exist for the regular G5RV AND the G5RV Jr.? Or at least the full sized version, I guess it could always be modified to fit the Jr. I've attempted the full sized G5RV model with strange results (again my skills are not too good, but I keep trying anyway).
- The full sized G5RV definitely has different characteristics over it's smaller brother, or so it seems. The full sized one I have works well on 17, but the Jr. a friend has does not. Mine is so-so on 12, his Jr. works very well on 12. Does anyone really know why? Or is it just luck of the antenna?

Thanks!

========================================

Measured values of Rho greater than 1.0 are not necessarily due to
measurement errors. They can be true. The true theoretical maximum value of
Rho is 1 + Sqrt(2) which occurs on transmission lines only at extremely low
```

frequencies and with a purely inductive terminating impedance. It arises due to resonance between line impedance and the termination and cannot be of any consequence at RF.

Values of Rho greater than 1.0 are mathematically legitimate as may be demonstrated by exact computer programs when presented with exact data. In any case, the Smith Chart is inherently inexact at the lower frequencies in addition to the user's difficulties of reading from it.

The reflection coefficient can quite easily lie in any of the four 90-degree quadrants. If the real component of the vector is negative it may be thought to correspond somewhere to an imaginary negative resistance. But when Rho is correctly used in line input and output impedance calculations it always gives the correct answers. ie., negative resistances cannot exist. Resistances are always lossy.

Yes, very much if things are this touchy. You are trying to feed a
high Z antenna into a low Z cable. Radio Shack has a very common
BalUn product designed to take care of this very simply (and using
common coaxial products they sell too).
>
>
>No active amplification is used.

That's fine, but by all of your accounts, you are on the thin edge.

>For now, primary Teri can live with this.

Hi Doug,

Teri may be able to get along with it much more, if you realized you
have two antennas in one and simply remove one of them. Simple, is
easier said than simple.

By all appearances you have a combination FM-TV antenna as I see at
least 5 elements (you don't show the entire antenna by the way) and
you are only using 3 of them. Your connection should be at the end
that is pointing (east) at the station you want to hear. If it is
not, you have it pointed backwards and this may explain why things are
so hinky. Another clue that you can verify. There should be another
set of antenna connections (like wing nuts that presently you connect
to) at the OPPOSITE end of the boom - n'est pas? They should be on
the next to last elements before the end of the boom.

Henry,
I would be very careful who are you calling cheater!
According to my records, WA0GOZ, you were sent few free issues in the beginning, never subscribed, never paid the dime.
Can you send me label from your last issue and how much do I owe you? Now I can refund anyone requesting so.
Interesting that most noise about Radiosporting is made by people who didn't subscribe but are somehow "cheated".

For your information, I "invested" over $70,000 of my money and sleepless nights into publishing magazine that would serve DXers and contesters. When due to financial, family and health reasons I could not do so anymore, no one came forward offering help, NCJ went in competition to "bury" me rather than cooperate, I am glad to be still around and not joining likes of late W4AN.
Just read the crap on eHam.net when W4AN was in bind, requested some help and bunch of whiny cheap hamsters drove him off, rather then contributing and helping someone who was so dedicated to our beloved hobby. There are quite a few sickos around and they project themselves with their postings.

You can accurately mathematically model a G5RV (and any other dipole with any feedline, coax or not, tuner and balun) using program DIPOLE3.

But a G5RV, with its coax, has a somewhat worse performance, on the average, than any other multiband, random length dipole. Without the coax it is exactly the same as any other multiband, random length dipole except that, merely to preserve its name, you are stuck with a feedline that must be exactly 1/2-wave long at 14.15 MHz. Which is never the right length for your backyard and shack.

As for the 'Half-size" G5RV, its the biggest joke ever played by manufacturers and salesmen on ex-CB'ers and novice purchasers.

G5RV himself, a true, venerable, grand old gentleman of amateur radio, must squirm in his grave whenever the description is mentioned.

Download program DIPOLE3 from the website below in a few seconds and run immediately. No unzipping inconvenience. In view of the advertised popularity of the G5RV the basic data can be entered in the program with a single key-stroke.

You must enter data for the 1/2-size G5RV, or any other dipole, yourself.

Incidentally, the best performance multi-band dipole is of a random length which fits into your back yard, fed with any random length of 450-ohm line, or a 500 or 600-ohm open wire line, which also fits in your back yard, in conjunction with a tuner. Spend your money on the tuner. Simplicity Invariably Rules!

Yuri, I agree in general with your, not out of place, semi-technical sentiments.

But regarding lossy wires, laid on the ground, as for a Beverage which is often supposed to depend on ground loss, we must be very careful of making a virtue out of a vice.

I venture to say the higher an LF Beverage was above the ground the more efficient, both on receive and transmit, it would have become. The reason a wire as long the Beverage was so near to the ground was because of the high cost of a lot of very tall poles.

The rest is old-wives' tales.

Or have I inadvertently changed the subject?

Reg.

To be fair, W8JI usually slowly moves himself off his always/never
rail position to a more reasonable often/hardly-ever position. Some
time ago, he and others on this newsgroup asserted that absolutely
nothing changes when one moves the balun from the tuner output to
the tuner input. The subject came up recently on eHam.net.

> W8JI wrote:
>> If you draw a floating network on paper and look at what happens,
>> you'll see moving the balun results in the same stress on the core
>> regardless of the side of the tuner the balun is on.

i.e. a paper solution indicates that nothing changes, but ...

>> In real life, stray capacitances from the network to ground modify
>> the behavior of the system when the balun is moved, but the change
>> is generally both small and unpreditable.

i.e. changes can and do actually happen in the real world.

As in any distributed network configuration with reflections, if the
balun changes the phase between the forward common-mode current and
the reflected common-mode current, that can shift the location of
the common-mode current nodes.

Antennas are scalable with frequency. The full-sized G5RV is a
pretty good performer on 80m, 40m, and 20m (also 12m). The 1/2
sized G5RV will therefore be a pretty good performer on 40m,
20m, and 10m.

I'll just take a guess.

If you take a half-wave dipole and gradually bend it into a circle, then,
for a constant current, the field set up at a distance will crudely reduce
in proportion to the direct distance between its ends.

The greatest distance between its ends is when it is just a straight wire.

Reg.

Reg,
the subject of discussion on TopBand reflector was conductivity of earth under the beverage or effect of wire placed on the ground and its effect on the preformance of the Beverage antenna (above). Here is the repeat of W8JI portion of the posting on this subject:

>>The only thing that prevents people from shooting themselves
in the foot with the wire below the Beverage is the wire
couples to the lossy media below it so well it becomes very
lossy, and of course that means it doesn't help with
stability or termination.<<

- "" wire below the Beverage"" there is aconsiderable discussion on this subject there.
My problem is with the statement " the wire
couples to the lossy media below it so well it becomes very
lossy"
As far as I know, to make wire lossy, one must increase resistance by some means. In my book, wire maintains its conductivity regardless what it is laying on, and that overrides the effect of lossy ground underneath.

Speaking of Beverages and their poor performance over good ground or salt water, most people find it is true, some claim still good performance on LF and MF. While operating from VE1ZZ place and using his beverages, he has one that is running over the rocky ground, slightly down hill, 90 deg towards the salt water and it is terminated via resistor into the stainless steel hubcap in the salt water. That sucker beats anything else we tried, pair of staggered beverages or phased ones. So it appears that Beverage stretched over poor ground but terminated in the good ground beats their "better" cousins. We are talking about 160 - 40m and definitely not using it for transmit.
This is reality in by old wives.

Judge by yourself, here is the complete posting, rest of the discussion is on
http://lists.contesting.com/archives/html/Topband/2004-08/index.html
Yuri

> I'd say that given "average" elevation angles for DX, you
should treat both
> arrival elevation angle and tilt from ground loss as being
roughly equal
> factors.

None of that matters anyway Chuck when the pattern of the
antenna isn't any good. We know a lot more about antenna
patterns and how antennas respond over earth than we did
back in the earlier part of the 20th century.

The fact is we want the horizontal area of the antenna to
have as much response as possible. If we put a wire below
the antenna that *really* changed things we know by where it
is located it could only make things worse.

A Beverage responds in the horizontal area only because of
the high loss in the media below the antenna. Without a
highly conductive media below the antenna, it's a cloverleaf
with a null off the ends caused by the vertical ends
dominating the response.
It's all in the antenna pattern. We can have all the tilted
wave we like but if the antenna has a zero response slice
looking at it and major lobes 20dB stronger 45 degrees to
either and off both ends, we won't be very happy with the
results.

The only thing that prevents people from shooting themselves
in the foot with the wire below the Beverage is the wire
couples to the lossy media below it so well it becomes very
lossy, and of course that means it doesn't help with
stability or termination.

If you think it does, lay a very long wire on the ground and
measure the input impedance. See how it looks compared to a
~50 ohm ground rod connection....I guarantee it won't look
pretty.

Hi Mac,

The danger of this is these "arguments" (offered on the behalf of a otherwise silent party) is that they have every chance of being under reported, and over extended. It quickly devolves to "so-and-so thinks...." to triumphantly prove it-just-ain't-so.

It reminds me of past statements offered as V9SRB's logic in his behalf that never were suggested by him nor even intimated. As a one-time shot against a full statement, I suppose that is enough to critique, but I have seen this hothouse orchid bloom into fully fleshed philosophies projected onto the silent protagonist by unrelated statements forced into continuity by the critic presuming a sub-context.

If Yuri, you have some beef against Tom, I can fully concur in his personality taking you there. Has he offered howlers? You bet! Is he guilty of other rhetorical shenanigans - don't we know. Is he demonstrably skilled? Well, yes, that too.

[warning to readers, metaphors employed to a sly comic interlude]

Suffice it to say no Radio Moscow program ever interviewed a Radio Free Europe commentator to serious issues - why would you expect such a re-alignment of the heavens for your sake?

Ask George W for help; you might find he would take on the evil Dr. Joyce Brothers to solve our moral problems with Howard Stern. ;-)

Dear Richard and others:
You have helped me to understand what the issues are likely to be,
what they could be, and even a glimpse of what they might become.
I shall file in my list of
interesting-things-to-think-about-in-a-serious-way the issue of what
happens to the behavior a wave antenna having a "wire" on the ground
directly under the antenna wire. I do recall dealing with a similar
issue where I was verifying a modeling issue by testing the Zo of a very
long wire over a conducting plane. Might be a paper in there somewhere.

It reminds me of a fundamentals of mathematics class that I took
from Prof. Halmos. Perhaps his greatest genius was his ability
frequently to suggest interesting problems.

I shall exit stage right 'till I have "thunk" through the
interesting bits. Thank you for your assistance.

Hi Mac,

Where the discussion remains technical, it seems to me that both Tom
and Yuri are saying the same thing. On the other hand, they may say
it differently, but the conclusions seem to agree.

Your experience and studies to this point would be instructive.

you'll find as the height of the antenna increases, the need for a
'sweet-spot' decreases - because the sweetest spot is up high.

I was under the impression that radiation efficency was pretty much a"
no-brainer".If the antenna is built of quality materials with good
workmanship the antenna would be an efficent radiator with little ohmic or
dielectric losses. The exception to this of course would be antennas that
use an earth ground. I just found I was losing at least 3 db to heating up
the ground.

Keep digging, you will find more lost dBs. Things get aggravated in loaded antennas when you start inserting coils, loading elements, folding them back, etc. Efficiency is roughly proportional to the area under the current distribution curve along the radiator. That can be affected by any of the shortening "miraculous" gizmos, like Vincent DLM antenna. It is not just heat loses in resistances. You can't have "perfectly" conducting piece of 1 ft copper tubing be as effcient as 130 ft full size radiator on 160m.
Getting smarter, Eh ? :-)

Hmmm...isn't the "claim to fame" of the Isotron the small size? A 6M loop is going to be small...look at the halos and omnis like the PAR OmniAngle...quite small footprint. Heck, I use a travelling dipole made from two RatShak 72" whips in a block of nyloc! Think it would be better to "roll your own" in this case. Do a search for 6m halos or go to www.cebik.com for some good 6M antenna info. If you prefer not to roll your own, there are some excellent loops out there...I have several homebrew loops and one of Dale's fine Stressed Moxons for my 6M solutions.

Hi Jimmie,

3dB heating up the ground with an antenna that has 5dBi gain in the preferred direction and launch angle compared to an antenna that has no ground and 0dBi gain in the same preferred direction and launch angle may give you pause and allow the worms some comfort on a cold day.

Workmanship and quality materials tests those reputations vastly more for smaller antennas than standard sized ones. Those 1 meter loops used for HF are not rated for the lower bands for very good reasons, and they claim (and I believe them) high standards for their product. However, if you could resonate them in the 160M band, you'd be lucky to see 1% efficiency.

Small antennas carry a lot of baggage, and any claims of efficiency superior to the standard antennas they replace are suspect. When they qualify that efficiency in creative terms like "more efficient per unit length" you would do well to skip that and ask for field strengths out 10 miles. A model called the eh had an FCC style site survey performed to which they crowed it proved their design was equal or better to a full size antenna. The data revealed results 10 and 20 miles out were 15-17dB down below that same standard they were so much more efficient than.

You would be lucky if you could get 10 % efficiency at 40 m for these
1 m loops. Since the radiation resistance is inversely proportional of
the fourth power of frequency and the skin effect losses proportional
to the square root frequency, one could expect to get nearly 1 %
efficiency at 80 m and well below 0.1 % efficiency at 160 m.

On the European 135 kHz LF band, the practical vertical antennas are
usually less than 0.01 .. 0.02 WL, the estimated efficiency is less
than 0.1 %, so more than 1 kW has to be driven into the antenna to
even get 1 W of ERP. This 1 W ERP limit is used by many countries and
still narrow band contacts of several thousand kilometers are made.

Unfortunately, trying to compensate the low efficiency in a small
magnetic loop with a high transmitter power is not very practical,
since the voltages would be huge.

Thus, if some exotic small antenna with inevitably low efficiency is
to be used, I would first check that it can constantly handle the full
legal limit power, so that it would be possible to compensate for the
lower efficiency.

The low antenna efficiency is not much of a problem in receiving on
LF, MF and lower HF frequencies, since the band noise is still well
above the receiver front end noise. However, on upper HF and above, a
low efficiency will degrade the reception, especially if the receiver
noise figure is high (which it often is in HF receivers that try to
maximise the intermodulation performance).

Certain products that include antennas may have to be tested for emissions
on a standardized site called an OATS, but that is a very bad choice for

antenna measurements (distance is 10 meters at most, and there is a perfectly conducting ground plane).

As an engineer, I prefer to see performance data obtained in as simple an environment as possible. But as a ham, I also have to admit that most people don't use antennas under "test range" conditions. I can easily imagine an antenna that looks good in "test range" conditions, but is badly influenced by real-life items like proximity to ground, chimneys and trees.

Does the FCC (or anyone else) define any standard site for measurement of antennas? Could the closest thing be NIST's antenna calibration ranges?

Wow, that's looks like hard proof to me. Now Yuri can refund a couple of dollars to Henry, gain spiritual peace over resolving that debt from 1989, and the world will be a better place for all.

Maybe I could get all those deceased computer mags from the 1980's to refund their defaulted subscription balances to me, and I could go have a magnificent banquet dinner for two at McDonalds.

No, the idea is to invent something, make it, sell it like hotcakes, and
then sell the business when all the me-too's show up. The patent is just a
very time-consuming & expensive official license to sue whoever appears to
be improperly competing with you. Your lawyer may not help you with circuit
design, but he will advise that you go for a patent.

I looked up the dielectric constants of a few materials:
http://zhangzc.jahee.com/chemcai/Dielectric%20Constant%20Table.htm

air ~1

or

paraffin wax 2.1-2.5
beeswax 2.7-3.0 very close to paraffin!
urethane (not foamed) 3.2 (polyurethane?)
cast epoxy 3.6
polyvinylchloride 3.4 (common wire insulating material)

Potting a balun coil in these materials does substantially increase
stray capacitance.

The mil. circuits I saw potted in wax or paraffin were audio, not RF.

I guess foamed polyurethane has a modest dielectric constant.

I read that some commercial RF transformer (e.g. RF System's so called
Magnetic Longwire Balun) are filled with polyurethane foam. I also
found a 4X ham discussing and blessing PU foam at
http://lists.contesting.com/archives/html/Topband/2003-11/msg00038.html

The same article also warns against potting in epoxy, as it boosts
stray capacitance in transformers designed for air insulation. Wax and
paraffin are better than epoxy, yet they may both be troublesome.

The PU foam I can get is the common consumer "monocomponent" type. It
is a misnomer, as it requires ambient humidity to react and cure. It
will not properly foam inside completely closed environments unless
water is provided.

I tested foaming in a foot-long 1/2 in. plastic pipe, not pre-wetted,
and the result was that foam properly formed only for the first inch
or so at both ends, while the material collapsed into a film in the
middle.

Instructions correctly advise to 1) wet the surfaces the foam will be
in contact with, 2) if one needs to fill a deep cavity, deposit foam

in layers and allow each layer to set and dry.

The resulting foam is stiff and does form a light bond with plastic, but is rather easily removed if the need arises.

My balun box is small, at most 3/4" deep, all metal contacts are already coated with thin epoxy, and the transformer wire is PVC coated too, so a momentary contact with water spray, soon to be soaked up by the PU, should be OK.

I'll do another test in a small plastic box containing some wiring, all pre-wetted. As the foam keeps expanding as it sets it may be a good idea to avoid closing and bolting the box lid before it cured completely, or at very least to provide some escape holes. More later.

2236. Tuning Schumann coil?

Agreed. However, the PU foams that we buy in DIY stores do tend to soak up water into the outer layer, especially after the smooth surface has been cut to trim off any excess.

Some foams are notably better than others in this respect, and it might be better to look for the special 'closed cell' foams that are specifically rated for use in for flotation aids.

You can file patent yourself and it doesn't have to be very time and money consuming. In some situations it is worth it (Laser) in many situations patents remain unutilized. Often it is deterrent to me-too's and if you have a lawyer in the family, it could be reasonable.

Most test ranges are designed to measure (as accurately as practical) the radiation pattern of the antenna hardware alone, and normally in relative field only -- not in absolute gain.

The affect of the installation environment on the free-space patterns of an antenna vary widely. The azimuth patterns of FM broadcast transmit antennas are sometimes measured at the OEM's test range while mounted on a section of tower, and in the mounting configuration to be used for the final installation. That will show how the signal will be "launched," but gives no final data about how well the antenna will perform after installation. That will depend on its height above ground and propagation conditions along the path from the transmit site to the receiver.

Source record: 90563

I have a 135' long doublet, 45' in the air fed with 450 ohm ladderline. It tunes fine and works well through an MFJ tuner on all bands up to 21MHz. Above 21MHz I have a very difficult time tuning the antenna to get any SWR below 3:1. I cut 6' off the feedline when it was finally dressed into my shack and that made it worse. I have now reinstalled the extra 6' and that is better for tuning, but not yet perfect. I guess I'll just have to keep adding or subtracting small amounts of feedline to get it right?

If so, are we talking inches or what? Any ideas appreciated.

Hi Yuri,

As Mac said, there are many "its" in the quote. However the vague combinations do not resolve to different interpretations as you persist. The extra wire leads to the same conclusion you BOTH describe and that is Beverage-like antenna characteristics. As that is a unique consequence of ground's retarding the wavefront, it necessarily follows that Tom maintains (and directly states) that the extra wire does NOT interfere with that action. He states why - tight coupling. He no where states that metallic copper assumes ohmic loss as the loss is a consequence of proximity to earth. Further, I've seen no statement from you or Tom that maintains the extra wire destroys the Beverage-like antenna characteristic, hence there is not a hair's width difference between you two.

However the FCC does *not* require in situ measurements for the proof/operation of ANY transmit antenna used for FM or television broadcast -- whether required to be directional or not. If directional, the required pattern is defined in the license application/grant, and is demonstrated only via relative field measurements by the antenna OEM on his test range.

The reason is that the measured value on VHF/UHF can depend at least as much on the propagation paths to the measured points as the true radiation pattern from the antenna hardware itself.

In situ measurements are required for certain qualified bearings on the calculated radiation patterns of MW broadcast directional arrays, to ensure that co-channel interference is controlled. There really isn't another choice in this case -- the array is purpose-built on site. Erecting and testing it off site would not be practical, and the terrain likely would be different anyway. MW directional arrays also have means of adjusting the phase and power in each radiator to adjust the pattern values as shown needed by the monitoring point measurements.

Message-ID: <ecb0f5f9.0408230901.652bebe3@posting.google.com>
Source record: 90424

This is more of an account than a question but here goes. I have a second
qth in the Sierra at about 4000 feet. The soil is rocky and dry,
especially this time of year. Using a G5RV at about 40 feet in a tree
I was plagued by a surprisingly high noise levelon 80/40 meters. It
sounded like power line noise but I can't say for sure. Playing with
various grounding schemes seemed to help somewhat but never really got
rid of the noise. One scheme seemed to work for awhile and the next
week it didn't.

The solution was to close in the bottom of the G5RV forming a full
wave loop.
The noise is no longer discernible. It went from approximately an s-6
to zero!

My question is: What can I conclude from this? Either concerning the
nature of the noise or the efficacy ofthe solution. Loops is gud?

Aside, the loop seems to be good close in as it is fed from the top
(Like a G5RV) but I am considering a corner feed to improve low angle.

Hi Tony,

If it is a crackling noise, it is most likely static. Are you using a BalUn with 0 Ohms continuity across the feedpoint? If not, add one, or add a small resistor (10KOhm) across the feedpoint to drain the charge and make sure your set is grounded (to as good a ground as you used as a remedy before).

I bought an unused TA-33 at a hamfest. The elements telescoped together with a dab of colored paint on each piece.

A 4:1 voltage balun will also solve the problem or
simply an RF choke across the dipole feedpoint. The
problem is static electricity common in dry climates,
building up between the two antenna conductors, and
can be caused by wind or snow. It is enough voltage
to cause arcing across the coax connector. (Hint: The
quad was invented to solve a Yagi melting problem.)

Where is it fed? [center, end, off center, etc.]

If center fed, the impedance looking into the feedline exceeds the
tuning range of your tuner. I would start by adding a little less than
1/4 wavelength at 28.3 MHz of additional feedline [something around 6 feet].

I use a CF doublet with 600 Ohm tuned feeders and an OLD [OLD] Murch
UT2000A tuner with a very good balun.

Hmmm Sounds good , Put up a 1wl loop for 80 meters (274ft+/-)?
up 20 to 40 feet,feed it with ladder line or window line (61ft) into a
balanced tuner and rock and roll. Should be able to cover the entire
US on 40 and 80meters with some rather Brutal lobes on 20m.
You be Jammin!!!

I get consistent 9+5, 9+10 reports on 40m out 500miles with this setup on
10watts!!!!!! YMMV

Are you quite sure you have no way to measure inductance? Even if you have only an AC voltmeter and a signal generator and some capacitors, you should be able to measure the inductance. One of the best ways to "measure" it for your application is to try a capacitor and see what the resonant frequency actually is; then adjust the capacitor (by a factor equal to the square of the ratio of resonant and desired frequencies) and try again, repeating until it's trimmed to the desired resonance.

Cheers,
Tom

Is this radiation efficency or gain, y'all are talking about. Not familar
with the DLM but sounds like the MFJ loop. 10 db pad and a cb antenna would

work as good.

>I have no way to measure inductance.

To know what size Cap. you will need, you will have to have some idea of the inductance. One easy way to check the inductance uses an AC voltmeter a variable resistor (pot), and a low voltage 60 hz voltage source like a 120/12 volt transformer.
Hook the inductance and the variable resistor in series. Apply the 60 hz source across the series combination. Adjust the pot until the voltage dropped across the pot and the inductance are equal. Read the value of the pot, this is now equal to the inductive reactance of the coil Xl plus that 18k DC resistance you said you measured. From this you should be able to calculate the approximate inductance of the coil, and the Capacitor value needed to tune it to 8 hz.
Use L=(Xl+18k)/2*pi*60
and then 8^2=1/4*pi^2*L*C and solve for C.

2269. Stainless Steel Wire - OK for antennas?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-23 22:11:53 UTC
From: Dave <dave@somehere.net>
Message-ID: <olqki0pet45df00vbc4fltdqkhkeajmg5q@4ax.com>
Source record: 90440

I recently acquired a large quantity of very flexible stranded stainless steel wire at a garage sale. It is about 0.85 mm (around 1/32 inch) in diameter and extremely strong. I was wondering if this could be used for wire antennas for HF. I seem to remember seeing something about SS not being ideal. Is this a real consideration or just a matter of being too finiky?

Thanks - Dave

First of all, I have not done experiments to compare single wire Beverages vs. dual wire, with the other wire being laid underneath the Beverage.
I had the problem with statement "the wire below the Beverage is the wire couples to the lossy media below it so well it becomes very lossy" as far as I know wire maintains it's conductivity regardless where it is laid. Perhaps more accurate statement would be that wire laying on the ground becomes less significant in its contribution to the performance of the above Beverage.
But because the "ground" wire is connected typically at the termination point and at the feedpoint to the Beverage system, I am not sure that it can be "ignored". Some claim this forms the "open wire" parallel system and has significant effect on the Beverage performance. There is dispute as far signal arrival angles are concerned, some signals get subjected to wave tilt due to poor ground, some signals have their own tilt due to propagation and terrain effects.
To find out the reality, the exact systems should be compared in various situations. Modeling might not provide fool proof answers due to some programs having hard time to model reality, that can be confused by varying ground characteristics along the Beverage.

>Above 21MHz I have a very difficult time tuning the antenna to get any SWR
>below 3:1.

Hi Larry, My good friend Reg Edwards pointed out some time ago that most antenna tuners give it up above 21 MHZ. This is due to stray Inductance and Capacitance in the Garden Variety Antenna Tuner. Makes it real difficult to tune certain antennas above 21 MHZ. As others have mentioned, change antenna length, or feed length and see what that does. There are programs that will determine correct tuner settings for a given impedance, I prefer the Smith Chart.
If you can determine the Impedance, R+/-jx of the feed point, there are a number of alternative ways of designing a matching network.

The best use of it would be for the Beverage receiving antennas. Extra resistance helps to retard the reflected wave and "sharpens" the pattern.

Otherwise it would beat the heck out of DLM, EH, CFA or Fractuled antennas.

Of course it could be used. The resistance loss is insignificant. It will actually increase your SWR bandwidth. Certain Comercial Ham antennas use a fixed resistor to improve bandwidth and lower SWR. So go for it and see what happens.

Gary,
This sounds like a good idea. Only thing I would worry about is that given
the dimensions of the coil, it may be resonant below 60 Hz.

Yuri
Wire conductivity may not be pertinent in this case as "coupling" can reduce
the applied current
I would be extremely surprised if Tom inferred that wire conductivity
changed.

Hi Tam, Well, guess you are right, the self resonant frequency of the coil may be below 60 hz and would make the measurements different, this compounds his problem.

OK, I've seen the responses that the G5RV ,and especially the Jr. variety, are below average performers. And that a center fed doublet with open line or at least something like 450 ohm ladder line is a better option as long as you have a balanced to unbalanced external tuner. I certainly won't argue that, but suppose I want to be able to use my Kenwood TS450sat's internal tuner (unbalanced input only), what are my options for a decent, simple multiband antenna (80/75,40,20,17,etc)? And, I understand that 'fan' dipoles can be effective (I have an Alpha Delta DXEE for 40/20/15/10, it's poor on 40 BTW). I don't have enough tress for multi element dipole anyway. Can a 'doublet' with 450 ohm ladder line to a 4:1 balun then coax to the tuner be effective? What would be 'ideal' dimensions for the doublet?
BTW, I did download the 'dipole3' program and my friend with the G5RV Jr. was VERY disappointed to learn that his Jr. wasn't worth a hoot, even though he has had fair success with it. Guess in the end it all comes down to what you have faith in :+)) . Nice little program, thanks for pointing me at it.

Fun to consider these things and ALWAYS to experiment. Cecil, I took to heart your 'l-loop' and modified one for 30 meters. I have had GREAT luck with it! Best thing I've tried on 30. Thanks!

Hi Phil

I guess I was one of the few that didn't have any problems with 17 tuning up either before or after the 160 coil. But if I recall, I have it scrunched up real tight too. Like I said, been awhile, but I hope to be back at it again before winter sets in. I just moved to a new house in a new state and know I'll have to retune that thing after moving it.

Good Luck with it!

Following on the subject of coil loads on radiators I saw a mobile end fed dipole with a single loop at the center (cell?) It occured to be that the loop contained a capacitance of value dependent on the "pitch" of the loop as the loop was not "closed"
Does anybody know what the addition of the loop was for (phase change?) and its radiation addition to the dipole?
Note that the addition of another coil to the loop would change the impedance immensely. does the said loop encourage perpetual motion that Roy talked about?

Ok Gary, thanks for the info. I may get ambitious enough to retune the thing using the right equipment. So far I have just used the exciter output. I suppose realistically speaking, 17 through 10 will not matter much in the next few years. The thing is impressive on 160, though, and that was the main idea.

73,

Phil - N1KI

Careful with CL fence. It may work, but older fence may turn out to
be hundreds or thousands of tiny diodes at the points of contact where
the fence is woven..

When we had the repeater here I found a 10" piece of wire laying
against a guy wire created enough noise to drowned out a 50 watt
mobile less than 5 miles away.

I could do the same with a 10" screw driver by just sliding it up and
down the guy. The end of that guy was grounded' too.

OTOH you are rarely listening while transmitting on HF so the noise
probably wouldn't bother on receive (unless your neighbor is trying to
listen to the AM broadcast band<G>)

Yuri

I wonder where the power into a perfectly conducting 1 foot length of
copper tubing goes if it doesnt get either radiated or get converted to
heat. Can you tell me how the short (1 foot) copper tube looses the power
it receives from its power source?

Hi Yuri,

In fact, no one has said otherwise. It follows of common sense unless
ground were exceptionally conductive such that its magnetic field were
to compress the skin-effect layer of the wire. If that were so, it
would be a new world for us all.

>Perhaps more accurate statement would be that wire laying on the ground
>becomes less significant in its contribution to the performance of the above
>Beverage.

Quite so - if demonstrable.

>To find out the reality, the exact systems should be compared in various
>situations. Modeling might not provide fool proof answers due to some programs
>having hard time to model reality, that can be confused by varying ground
>characteristics along the Beverage.

C'mon now, with only two or three wires involved? The only problem
modeling programs have difficulty with are with modelers.

I compared two such designs. Nothing very involved with a 3M high
100M long Beverage operating in the 80M band (perhaps not long enough,
I will let others do their best if they find fault). I then compared
it with another which had a wire running below it 1cM above ground
level. The two showed more than 8dB difference with the ground wire
model clearly lossier (EZNEC declared at that same 8dB).

Now, I know that such antennas are not designed to be transmit
antennas (and again, perhaps too short to boot); so I will leave that
to others to engage as a receive antenna if they doubt reciprocity (or
I will do that later this eve for them as I often have to).

Yuri, the problem with you arguing Tom's position is that nothing is
said of this glaring difference. It is quite remarkable (or I made
some remarkable mistake or the wire is just too short as I mentioned)
and it DOES denote a dramatic departure from accepted Beverage
characteristics which has been undisclosed as a comment from Tom, if
in fact he offered it. This 8dB loss does make sense in that you have
a leaky transmission line in a death embrace with ground. The wires

would split the power and the lower power contribution would certainly attempt to warm the worms with more gusto.
[IF perhaps we were to employ the old twinlead twist every foot or so, we might find things evened out ;-)]

I will let that simmer for this evening.

For anyone who missed it, here is my previous posting on how to
optimize a full-sized G5RV for each HF band by changing the
length of the "matching section" per band.

These are actual measured values for the resonant lengths of the
series section transformer for all HF bands for my optimized G5RV.

102' dipole, insulated wire. Ladder-line is approximately Z0=380
ohms, VF = 0.9. Coax is RG-213

Freq-MHz ladder-line length
3.8 23 ft. (best with 1000pf in parallel)
7.2 35 ft.
10.125 20 ft.
14.2 29 ft.
18.14 36 ft.
21.3 27 ft.
24.95 29 ft.
28.4 38 ft.

wrote:

>Yes. No one is going to notice something less than half a dB (which
>by definition is unnoticeable).

This may be true for upper HF, but for MF/low-HF dipoles the situation may be a bit different. The dipole length is inversely proportional to frequency and the skin depth (and hence AC resistivity) is directly proportional to the square root of frequency. Thus the net effect is that the total dipole resistance is inversely proportional to the square root of the frequency. Thus a dipole cut for the lower band has a larger resistance than an antenna cut for a higher bands, provided that the same wire type is used.

The resistivity and skin depth depends on the material and apparently varies quite a lot depending of the type of stainless steel, since various sources give quite different values.

The skin depth for copper at 1.8 MHz is about 50 um, while for some stainless steel, it appears to be around 200 um. Both values are well below the OP's 850 um conductor diameter.

One source claimed that the stainless steel has a 52 times DC resistivity compared to copper, so factoring in the large skin depth, the AC resistivity at 1.8 MHz would be more than 12 times that of the copper wire of the same size.

An other source specified the stainless steel resistivity as 43E-8 ohm/m and while the 0.85 um diameter conductor with 0.2 mm skin depth would have an effective cross section of 0.4 mm2 and with the 80 m length of the 1.8 MHz dipole, the total resistance would be 86 ohms.

Compare this to the nominal 73 ohm radiation resistances for a half wave dipole and more than half of the transmitter power would be dissipated in the losses.

However, since the current distribution is not uniform along the dipole, the effective losses are not that quite as bad. On the other hand, if the dipole is close to the ground, the radiation resistance is well below 73 ohms, so again, we are in the -3 dB efficiency ballpark value.

With a 1500 W transmitter, the losses are about 1 W/m, this should help melting any frost accumulated on the wire during a cold night:-).

Now the question is, is this 80 m stainless steel strong enough to support itself, even if supported in the middle at the feed point.

For a copper wire with the same diameter, the resistance would have been below 10 ohms and the losses about 0.5 dB.

Hi Paul,

And still, no one would notice. In fact, I gave the loss 100 Xs
copper, lowered the frequency to 1MHz and saw roughly 6dB loss - the
"standard" S-Unit, against which propagation variations would toss
that around to wider variation. I suppose it wouldn't do for EME, but
I don't know any work at 1MHz for EME.

Still, and all, this determination is easily within the scope of the
free distribution of EZNEC which allows any user to make an informed
decision about a choice being OK.

The unit of resistivity is of course ohm m (not ohm/m).

>With a 1500 W transmitter, the losses are about 1 W/m, this should
>help melting any frost accumulated on the wire during a cold night:-).

With 50 % efficiency (-3 dBd gain), the losses are about 800 W and
when divided evenly along 80 m will give 10 W/m (not 1 W/m), which in
addition to frost will also melt ice and keep the birds away :-).

This isn't answering your question, but you forgot the effect of reflected power. I wouldn't call that "lost power", but it sure isn't contributing to the radiation.

Hi Jim:

Here's what I've done in the past and it worked well for me. (though I'm not sure about the tuner in the 450, but it worked fine with my LDG Z100 auto tuner) Run the best coax you can find.. try to keep it as short as possible (less than 10' would be good) to the outside of the building then use a 1:1 Choke balun and convert to open wire (ladder line) run it to the center of the dipole. then get on the air and use it, think you'll be happy.

That's what they use for mainstay antennas on yachts. they work well (the groundplane helps of course).

Remember, a terminated Rhombic radiates essentially
in one direction. Removing the termination allows
reflections to take place thus also radiating in the
opposite direction, the direct result of radiation of
reflected power.

Of course, depending upon the impedance seen by the choke, the
choking function may be virtually non-existent. For instance,
5000 ohms is not an unusual impedance in a system of this sort.
The choke would need about 25,000 ohms of choking impedance. I
don't know where to obtain such a choke. I'm doing good to get
500 ohms of choking impedance. If I ran a system such as above,
I would definitely use a balanced antenna tuner.

There absolutely are "sweet spots", but how do you find them?

I think the most fun working with antennas is the unknown. After all
the formulas and calculations, the tuning, the trimming and tweaking,
etc., the element of chance enters the picture, where you put the damn
thing :-)

It's like flipping a coin, I guess.

Hi All,

I have some info on a Beverage antenna that I believe you'll find interesting.

During 1942-43 I was with the Radio Intelligence Division of the FCC in Hawaii, monitoring enemy transmissions. One assignment by the State Department was to determine whether the Japanese in Japan were getting the same information from their local broadcasts as the propaganda broadcast on HF, or different information concerning the progress of the War.

On searching the AM broadcast band for Japanese stations we found JOAK, Tokyo, on 650 kHz, with an exceptionally strong nighttime signal. However, KNX, Los Angeles, also on 650, was equally strong, making copy of JOAK impossible. Consequently, two of my colleagues, Prose Walker, W4BW, and Edwin Rudisuhle, K6SAC, installed a Beverage antenna on the northern shore of Oahu to reduce the interference from KNX. The Beverage was more than one-half mile long at a height of 10 feet, aimed directly at Tokyo, and terminated with a variable resistor. The signal from KNX was totally nulled out with the adjustment of the terminating resistor.

The State Department was pleased with the results, because we were then able to record the JOAK broadcasts daily, with the records sent to Washington daily by US Army planes from Hickam Field, Honolulu.

Cec, if the circuit impedance at the location of the choke is so high that
the extra impedance of the choke is ineffective, then the current must be so
small a choke is not needed anyway. So what are you worried about?

Reg.

Here is the perhaps the best outline of the "problem" by VE7DXR and you might want to try to plug it into program to see the correlation.
Yuri

>>Observations done here 8 and 15 years ago using a 600m Beverage on the MW broadcast band seem to verify the above statement. Even though the DC resistance of the wire is naturally very low, it was found that the "counterpoise" lying on the ground underneath the antenna, and connecting the ground rod at the far end of the Beverage with the ground rod at the receiver end's matching transformer, in fact, was acting like a "Beverage on Ground", rather than a short circuit between ground rods. That is, it delivered a signal to the grounded side of the matching transformer. The result was that signal strengths often were stronger from transmitters broadside to the antenna (10 dB or so), the occasional solid nulls on signals from the back of the antenna were degraded, and little increase in signal strength from signals from the far end of the antenna were observed.

Those of us who performed this experiment stopped using "counterpoises" from that point forward, unless we used them as antennas in their own right.
best wishes,
Nick, VE7DXR<<

Yes, try adding some feedline.

I have a ~120' doublet center fed with ladderline. No problem matching it
on 80/40/20/15/10 with a Johnson Matchbox. But I did have to change the
feedline length from what I started with.

2312. Re: Butternut HF9V

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-24 14:33:38 UTC
From: raiar@bbs.galilei.com.nospam
Message-ID: <412b4b06.436016984@news.galilei.com>
Source record: 90483

Hi Phil

The bandwidth on 160 was so narrow it was basically only good on one single frequency for me. Which was OK, I set it for a specific frequency I used twice a week.

All of my other 160 work was done on that Linear Loaded Inverted Vee that I put up. I had pigtails on it and set each leg at a different frequency and it still worked OK for me.

As far as the HF9V I was and am still very impressed with how well this antenna has worked for me. Especially in the confines of my suburban yard with antenna restrictions up the wazoo.

But FINALLY I moved to a new state, I live in a valley between the Cumberland Plateau and the Smoky Mountains, due to the hill behind my house, sunup isn't until around 9AM. But it is a very high hill and THAT is where I plan on building my antenna farm.
I've made many calculations and studied the lay of the land several times, it looks like the ideal spot for this area.
My only concern will be the coax loss in running over 600 feet of coax up the side of the hill. I would need 9913 for the upper bands.

I'm also looking into the possibly of using perhaps a 6 inch wide ladder line. But I'm not savvy enough to know if I can run coax out of the shack to ladder line for 500 feet then back to coax to feed the antenna towers. This is something I will have to study up on again before attempting it.

I may try a trick a neighbor about a mile away has done. We have extremely tall poplar trees here. He cleaned the branches and topped one of these poplars and then installed a 25 foot tall mast at the top of one of them for his VHF/UHF antennas. He said it's been up there for over 5 years and the new branches that sprouted have not come close to the antenna yet. So that might be one alternative for me to try also.

The HF9V will be ground mounted at the dividing line between my front lot and my back lot, which is only partially up the back hill in a flat clearing where I have plenty of room to run my overkill radials.
At my last home in St. Louis, I had over 3,500 feet of radials, some extending through neighbors yards until they reached the streets on the other side of their houses.
And, where backyards meet, many had those stockade fences and they allowed me to run dipoles across their backyards about 10 feet above the fence lines by installing 25 foot poles affixed to the fence

posts. POed the telephone and cable TV people who had to watch for my lines when working on the utility pole mounted services within their easements. I was not within their easement so they couldn't just knock them down and leave them laying on the ground, hi hi.....

It was so long ago, I don't remember which bands these apply to, but those horizontal metal strips on the antenna. On the upper one (after installing the 160 coil) I took a pair of alligator clips and a piece of wire about 4 inches long (2 inches each side) and experimented by making this top bar a little wider. I do remember it worked for whatever reason I was doing it. So I drilled two small holes in each end and laced a new copper wire through this allowing about 1-3/4 inch extending beyond the natural length of this horizontal antenna member. But I believe this may have been to use an out of ham band frequency for our emergency communications. The antenna was up for several years, so you tend to forget things you had to do when it was initially installed.
I never had problems with it, so I never messed with it.

It seems there are some photos on my web page somewhere, but I don't know if they include the HF9V or not.
The URL is http://archimedes.galilei.com/raiar if you want to have a look around and see. I'm quite lax on updating my web page, and it seems I never remove anything, just add from time to time. So there's no telling what you may find there.

My impressiion is that ladder line or balanced line is advantageous when the
line is run at a high VSWR. The low matched loss then also means a low loss
when run at high VSWR.

Hi Yuri,

I don't see how. On the face of it, it doesn't make sense.

>>it delivered a signal to the grounded side of the matching transformer.

It is all fine and well to observe that a wire draped along the ground
picks up signal (such an antenna I have seen "named" the Snake in the
Grass Antenna which is more an open terminated coax). However to
proudly state that it delivers it to ground begs the obvious comment
"how do you know?"

You must in fact break the connection, insert a load, and this means
it no longer delivers it to ground (can't have your cake and eat it
too). Such receive antennas are admittedly poor in efficiency but
useful as "quiet" antennas (where the receiver gain makes up for low
efficiency).

To cap it off, what is the "problem" anyway?

There's no such things as 72 or 75 ohm ladder line.

Ladder-line wires are spaced much too far apart and have mostly air insulation. They have impedances from 300 ohms and upwards.

Expect to find very low impedances only with twin-wires embedded in a thick, circular or elliptical PVC sheath. Loss per unit length is quite high and suitable only for directly feeding, resonant, single-band, 1/2-wave dipoles at the lower frequencies.

Zip-cord and twin speaker cables have Zo between 120 and 135 ohms. 16 to 20-gauge, colourless, speaker cables make a fair compromise between impedance, loss, SWR and small size. And exact impedance values are never critical at HF.

Worth an epic poem!

I particularly liked the bit about the wailing and the hair removal.

Yes, I was already rather concerned about this. The so called
"mono-component" storebought PU foam is sometime better referred to as
"waterblown". It's rated 90% closed cell, which is fine giving the
tiny size of the typical cell and the all-around sealing I am going to
provide anyway.

The problem is, the expansion ratio is hugely unpredictable. It is
said to go up from 8 to over 20 "if water is present", with "present"
being left undefined, and probably undefinable as well, although
"wetting" is recommended.

Moreover, as the unlucky canoe builder found, penetration, bonding,
expansion, and setting go hand in hand, meaning the stuff performs
this remarkable routine:
- penetrate every nook and cranny
- soak up water
- stick to surfaces
- gain some texture and firmness
- arch its back and expand (for waterblown: at some ill defined rate
too!), bending out of whack anything that is not as firm as stone or
steel

I did a test in a small box (translucent, probably polyethylene,
formerly contained a bike tyre repair kit). I put in a couple of
airwound bare copper coils, half inch apart, rinsed it all in water,
and while it was wet I sprayed in some foam (_not_ to the point of
filling it), closed it, and wrapped it tight with wire to provide real
closing power. I could see that the foam had not yet filled the
cavity. The DC resistance between the two coils had dropped from
unmeasurable (>2Meg) to 150k.

24h later, resistance was back up to unmeasurable, the box looked
completely filled, nice big round blobs of foam had formed all around
the lid, and all the surfaces of the box had become warped under
pressure. Chances are, the coils had been bent around as well - I

could not check if they were short of a CAT scan, for which I am not yet equipped.

If I'll do foam my balun box - and it's still a big if - I'll first fashion and fit a temporary, ~50% perforated lid, to give the foam an easy way out, and to make it easier for me to remove the excess foam later on.

I'll be very careful if I ever have to do the same to a canoe.

Thanks to all who replied. The static roblem is one I hadn't thought of.It is indeed a "Crackling" but is also very constant, unlike an arc followed by some quiet. For what it's worth I had the powerline company check and they said it was "Clear for miles". Oh well. The balun/choke/resistor is easy enough to try.I'll report back on what I find. Thanks!

==========
Dear Cec,

Just another comment about your oft-described high-impedance choke problem.

In all these discussions the LOCATION of the choke along the transmission line is always neglected. Yet its location is as just as critical as its value. If critical it is!

If a two-wire, unbalanced-to-balanced choke is deemed necessary then it should be located at a lower impedance point in the system where it is effective.

On the other hand, because very high impedances occur only on sharply resonant lines, problems may occur, if they ever do, only at rare sharply defined locations which can usually be ignored even if a resonant frequency should occur in an amateur band. An operator would very likely be unaware of it.

What would be the symptoms? Increased RF in the shack?

The solution of such a rare problem, if it occurs, is just to change the length of the transmission line by a small amount. But you are accustomed to doing this anyway to save yourself the cost of a tuner. ;o)

Changing the line length will shift an offending high impedance point away from the choke location.

This very moment it has just come to my wandering mind that you are in the habit of deliberately changing line length to bring the impedance down to a value between 25 and 100 ohms at which a choke is certainly fully effective.

So your worries about obtaining an exraordinary high inductance choke really don't exist.

(Just to tidy up, the length of wire on the choke should ideally be less than a quarter-wavelength otherwise funny effects occur. And this places a limit on its inductance. But that's just another factor which contributors to the argument seem to be unaware of.)

Yours, Reg. G4FGQ

Interesting and informative post, Gary. It seems we live about 35 miles apart. I am in Kingston. I can appreciate your terrain. I have tried several 70 cm skeds and finally had success on one into north GA. I usually tell anyone who asks that I am blocked in every direction except up. Of course, that isn't all bad since one of my main interests is 2 meter EME. I visited one of the locals on top of one of these hills a while back, and he had an S-9 noise level on 2 while I had very quiet condx at my QTH.

The narrow bandwidth on 160 isn't much of a problem since I primarily operate cw on HF. I began chasing a DXCC on 80 CW earlier this year.

You've gotten a lot of conflicting advice. Let me add mine.

Without going through the numbers in detail, Paul, OH3LWR's analysis looks sound. However, he neglected one factor. The skin depth is also inversely proportional to the square root of the permeability. Some stainless steels are ferromagnetic, with a permeability I'd guess at 100 or more. That reduces the skin depth, and therefore increases the RF resistance, by at least a factor of 10. If you do the analysis with realistic numbers, you'll find that loss can become at least several dB if the wire is magnetic, and worse with longer (40 or 80 meter) dipole lengths.

So my recommendation is to check the wire with a magnet. If it's magnetic, expect longer antennas to be quiet and broadband (which amateurs crave) but lossy (which most don't seem to care about). Non-magnetic stainless isn't likely to produce objectionable loss, except perhaps at an 80 meter dipole length or longer.

You can get a qualitative feel for the loss by comparing the 2:1 SWR bandwidth of an antenna made from the wire with the bandwidth from a dipole made from copper wire. The broader it is, the lossier it is.

Roy Lewallen, W7EL

More succinctly, it all boils down to -

Copper antenna wires are so efficient (say 98 percent) an increase in loss
by 10 times (down to 80 percent) is not noticeable.

My skin depth figures are base upon a quick web search, so I have no
idea how typical these figures might be or is it likely that the OP
would have a similar wire.

>If you do the analysis with
>realistic numbers, you'll find that loss can become at least several dB
>if the wire is magnetic, and worse with longer (40 or 80 meter) dipole
>lengths.

If my original assumptions are correct, the original poster (OP)
should also check the dissipation of each meter of antenna conductor,
since above 1.8 MHz, it appears that the power dissipation per meter
is slightly higher than at 1.8 MHz, thus the wire temperature is
higher (and might even affect the sag of the wire when
transmitting:-).

>So my recommendation is to check the wire with a magnet. If it's
>magnetic, expect longer antennas to be quiet and broadband (which
>amateurs crave) but lossy (which most don't seem to care about).
>Non-magnetic stainless isn't likely to produce objectionable loss,
>except perhaps at an 80 meter dipole length or longer.

In addition, since the OP had a large quantity of the wire, I would
suggest building a conical dipole antenna from the wire. Not only will
the current (and losses) in each leg be lower, but also the bandwidth
would be larger.

I'm not sure I'd trust my power company to say that they're ok. If you don't have a small battery operated SW receiver, get one. I have an old Sony model that turned out to be a needed piece of test equipment. I've used it several times over the years to localize QRN from the power lines, often right to the pole. When I could be specific about where and/or what the failure might be (leaking insulator, cap, transformer, ground/guy wire ect) , I usually got a quick response as this could be an indication of a more serious power line failure than just a complaining ham...

Getting a _balanced_ feeder at such low impedance levels is quite
challenging, since a typical twisted pair (e.g.CAT5) would be in the
100-120 ohm range.

You _might_ get something in the balanced 50-75 ohm range by getting a
quad-pair cable and connecting the diagonally opposite conductors
together. Thus, if the original pair had an impedance of 140-150 ohms,
the two pars in the quad-pair cable would give 70-75 ohms.

Beldin 8210, I believe discontinued, was/is 75 ohm twin lead; and, it
was quite popular 30+ years ago.

I haven't seen it in years. Last usage was in the 1950s on a 40 meter
dipole connecting to a pair of 807s in P-P with a Shielded Faraday link
to keep the TVI down.

Does this bring back memories among the 'old timers'?

W1MCE 50 years.

It may not be an answer to your question, but, 4 lengths of 75 ohm coax connected in series and parallel would result in 75 ohms, balanced. Two 50 ohm coax cables "paralleled" could provide 100 ohms balanced with the center conductors used as the balanced line.

If the current is small, the voltage is large and metal microphones
burn holes in my lips. Seriously, I still have a scar on my lip from
the 50's so you might say that's what I'm (still) worried about.

You're right, Reg, for you and me. But how about all the other
unwashed masses who are incapable of locating the common-mode
current-maximum point on their transmission lines? :-) What is
your advice for them?

The links to the patent application for the SteppIR are in the original post that started this thread. *Perhaps* what was new was the microprocessor control unit that can sit between the rig and the antenna and readjust the antenna as the rig is tuned. But since I haven't seen the RadCom one to which you refer, I don't *know* what is new in the SteppIR.

Some SteppIR antennas have been up for a year or more already and have survived high winds and ice storms, but I don't recall hearing of any lightning strikes.

The antenna itself has only beryllium-copper tapes whose length is adjusted by stepper motors, the latter being pretty robust devices by all accounts.

The sensitive electronics (microprocessor control unit) are in the shack rather than up on the tower, so the smart thing to do would be to disconnect and ground the control cable when not in use (after retracting the elements completely), just as one would disconnect and ground the feed line.

==========

They don't need any. The unwashed can consider themselves fortunate at
being unaware of a problem which doesn't exist if they tune up using the TLI
in their accustomed manner.

Imagined swr, reflected power, conjugate match and virtual open circuit
problems also vanish into thin air.

Please allow me to point out that 75 ohm balanced line is not
much better than 75 ohm coax. The key to reducing losses at
HF is getting the Z0 as high as possible, i.e. the current as
low as possible. Last time I checked, there was no 600 ohm coax.
What's wrong with this picture?

I am planning to put up an inverted-L along side my tower per the
drawing at

http://www.bloomington.in.us/~wh2t/invertedl.html

I would appreciate some suggestions for 12 and 30 inches stand offs
to support the 12g insulated wire I plan to use. Also the wire needs to
be secured at the top before it bends over. Any suggestions to keep it
from slipping at that point will be appreciated.

I plan to ball part the length at 130 feet and see what happens.

None of the usual suppliers carry anything but 300 & 450 ohm line
nowadays. I suspect the 75 ohm isn't made anymore -- it's pictured in
my 1985 arrl handbook, but nothing more recent. (The stuff is real
skinny -- about like zipcord.)

I'm not sure what the interest might be in the application, if a patent has been issued. Typically, an application undergoes modification -- sometimes, extreme modification -- before the patent issues. And only the patent carries any prohibition about anyone making, using, or selling the item.

The patent (6,677,914) is interesting in that it's a patent not for an antenna, or a method of tuning the antenna, but a system which includes the antenna, a transmitter/receiver, and "means to coordinate the means for adjusting the length of said conductive members to receive a desired frequency used by said radio transmitter/receiver." To see exactly what is patented, look up the patent at the USPTO's web site and read claims 1 and 16. Those describe exactly what is patented -- the patented system includes all the components in either claim. (The remaining claims are more restrictive, put there in case the less restrictive claims are deemed invalid in the future.) Only a system which includes all the components in a claim is covered under the patent, except for modifications "obvious to one skilled in the art".

DISCLAIMER: I'm not an attorney, patent or otherwise. This is based on my limited and layman's knowledge of the law. Don't regard it as legal advice -- see a qualified patent attorney if you need real legal advice.

Hi Dick, hope you get some good ideas for stand-offs - I'm building the same thing, but using a 90' tall loblolly pine branch, no stand-offs required ;-) I will use standing rigging and a nylon block (prob 4") to make the turn at the top (limb) as this minimizes overtensioning due to wind action between my pine-towers. And, I can always hoist a Balun up later , as below.

I have wondered what the performance difference would be between this Inverted-L (easy to erect) and the sloper or folded dipole, top-fed with a 4:1 Balun, but not as easy to fly. My 1/4~ will only be 107' so it's an easy job for the Inv-L...maybe I'll try the alternative if I'm not happy with it. But it it's not broke.....<G>

No Yuri, I was with RCA, the chief competitor of AT&T Communications. The RCA Communications system was on Long Island. The 100 kw transmitters were at Rocky Point and the receivers were at Riverhead. Each of these locations were huge antenna farms also, acres and acres. After satellites took over from hi-speed CW the Long Island operations ended and the acreage was given to the State of New York to be used as a State Park. However, the State wouldn't accept the property until all the antennas were removed at RCA's expense. This occurred in the late 1970's. A group of my colleagues went out there to pick up souvenirs. I have some 8" insulators used as separators for the long open wire transmission lines, and some of the 1/4" diameter copper wire used in the lines.

I should add that Dr. Beverage was the chief engineer for many years, and was also the one who designed the original system. Lot's of V beams and rhombics directed to many points on the globe.

Alan,
the article in RADCOM (UK) described the moveable radiator as a loop of material half of which contained a copper strip and the loop of material was driven by a motor such that the copper length was resonant.
Now a stepper motor is still an electrical motor which turns the shaft in a series of steps which is nothing unusual.
The use of a microprocessor to run a stepper motor is also normal as well as a comparitor system to control the length of the radiators to maintain resonance. There is also prior use of where the motors are enclosed and also controlled remotely.
Roy makes the point that the design in its entirety was the main claim which appears to be in the design patent bracket. Thus it would appear that the patent design in its entirety is protected which to my mind makes it one of the most weakest things to claim court protection but that is just my opinion. For amateurs who make their own antennas a patent does not really have any powers unless manufacture is a business.
It seems these days that those who move fast and take the cream and then quickly fade away can easily beat any justice system that reqiures a lot of cash and a strong push to get it moving on ones behalf. It is like the' pursuit of happiness' statement which gives one only the right to pursue but not to attain happiness"

The term "design patent" refers to a kind of patent that applies to an esthetic design, such as a unique shape for a vase or the classic Coca-Cola bottle. The patent in question isn't a design patent (even though the claims describe a whole system) but a "utility patent". Design and utility patents are different critters. Each has its own sequence of numbers, and I believe they have different application processes. When a technical person speaks of a patent, he or she almost always means a utility patent.

I know this to be true only for U.S. patents; I don't know about the rules or terminology used in other countries. You can find more information about the two distinct kinds of U.S. patents at the USPTO website.

In practice, you're largely correct.

In fact of law (here in the US), a patentholder *does* have the right
to forbid individuals from making and using a copy of the patented
device. You can build one to study it, or figure out improvements, or
figure out an alternative approach which isn't covered by the patent,
but the law says that if you actually make practical use of your
homebrew version of the patented invention, you're infringing.

As you say, this isn't likely to ever be enforced against individual
builders. However, there have been cases in the past where an
individual published plans in a magazine article, and the magazine was
sued or challenged by a patentholder for "contributory infringement"
(i.e. for inciting, encouraging, or enabling private individuals to
infringe on the patent, by building something according to the
published plans).

I've seen situations in the past where patent-holders have offered
individuals a royalty-free license to build a limited number of the
patented inventions, for personal use in a noncommercial context.
Sure seems like good, cheap PR to me!

I may be in error, but I THINK if you use 4 equal lengths of 75-ohm coax
with the shields soldered together - and then make them 2 'pairs' of
conductors - you'll end up with a 75-ohm balanced line. (You don't use the
shield as transmission conductors).
If I'm in error, I hope someone will correct me on this.
Thanks
Hal

I posted the same answer in his 'found' thread - but I wasn't sure if my memory was in correct operating order. At least your post gives me hope that my memory hasn't completely left me. :-)

I've used that scheme to make matching sections a few years back. 75-ohm cable comes in handy a lot of times.

From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cgh5nr$4ri$1@sparta.btinternet.com>
Source record: 90378

It will be of interest that if the inner conductor of 600 ohm coax is 18 gauge wire then the outer conductor diameter will be 22,000 times greater. ie., about 72 feet.

Not surprisingly, an 18-gauge wire at a height of 36 feet above ground has an impedance of the same order. Isn't it reassuring to see how things all fit nicely together.

Twinlead, ladder line, and other symmetrical lines are often called "balanced" lines -- as you've done here. But it's important to realize that there's nothing about these lines that causes the currents on the lines to be equal and opposite (or "balanced"). Imbalanced currents cause feedline radiation. Symmetrical lines can be unbalanced, and coax can be balanced. To learn a little more about this, see "Baluns: What They Do and How They Do It" in the _ARRL Antenna Compendium_, Vol. 1.

Oh, dear. I opened

ftp://users.aol.com/DGoncz/Antenna/

to add to my post, closed the window, and lost the post.

Rewrite:

The antenna, a Radio Shack 15-2163 6-Element Triple Drive Outdoor FM Antenna, is an open dipole having a characterstic impedance near that of the twinaxial cable. That's how I selected the cable. I matched the inner conductors and insulation to those of the flexible open dipole supplied by the OEM. The twinaxial cable has slightly thicker conductors, but the insulation on both is polyethylene, not PVC, and the spacing is similar.

The connection is indeed at the east end.

The lead hangs straight down now, and is lashed to a coat hanger wire narrow V that steadies the antenna side to side, preventing contact with the ceiling. The weight of the cable steadies the antenna. I propose a length of chain to lower the antenna to above head height to get it below the upper sill, and weights to level and balance it. That way it will rotate left and right a total of 360 degrees for testing, although it will only have one stable position. The cup hook in the ceiling appear secure. I have a plastic screw shield to improve the cup hook mount. It's in there with wooden splints now. Not bad, but not a hard mount.

The cable is under the rug now, avoiding another trip, which damaged the phone plug. A 5C collet and closer will straighten the plug. A cat toy house protects the cable at the transition to the floor. Tasha likes to curl up in there. They both bat the cable once in a while.

Yours,

Doug Goncz

Thanks, very interesting. Looks like the Ocean Gate site is probably the last one with chance to be preserved. Rhombics farm is on the marshes, dept. of wildlife and fisheries took over that, but antennas are still there. We are trying to turn it into historical landmark and get the museum going at the building. Hopefully also home for Tesla RC and do some operating from there. Still a chance.

>"sweet spots" that behave like funnels for radio waves?
....
>Ron, W1WBV

There are.
I would group them into two huge groups: one, large geography, two, immediate surroundings.

Geography and ground conditions can focus or disperse radio waves as well as contribute to the formation of the antenna pattern. Example would be antennas on sloping hills, bluff on the shore of ocean.

Immediate surroundings can cause reflections and sweet spots. Example I came across was small loop next to the Beverage. It had better performance than either lone antenna, better S/N. Another contributor are the guy wires, surrounding towers and anything metallic. Easily seen with mobile setup.

Dear Roy:
You have wondered about what the interest might be in the
application.

As you have accurately indicated, applications do sometimes undergo
extreme modification before one or more patents issue. Only the claims
in the issued patent constitute the meets-and-bounds of what is
protected.

However, comparing an application to the issued patent (or patents)
can be very revealing of the PTO's view of the subject matter. Insight
so gained can be of great help with further patent applications dealing
with similar subject matter.

In the days when it was not easy to compare applications with issued
patents, I had a case where a claim in an issued patent appeared to
encompass all archery targets having the appearance of an animal.
Paying to get a copy of the proceedings led to the conclusion that what
was actually protected were animal looking targets using two densities
of plastic! -- I have abbreviated the case --

The short answer is that one can (sometimes) learn from examining
the before and after.

To follow-up on another of your cogent observations: Design patents
protect the esthetic appearance of a useful article (and thus might not
be eligible for copyright protection) and their numbers start with a
"D." Plant patents have numbers that start with a "P."

Warm regards, Mac N8TT

Yeah, the idea does work. I am using two 'side by side' RG223s right now
to evaluate a dipole antenna I'm playing with. For my purpose, the 70 ohm
dipole on the 100 ohm line is a good enough match.

Hi Phil

As flat as Missouri is, my Creve Coeur home was in a virtual black hole. There was a microwave installation that blocked me to the northeast and several large steel buildings between my house and our local repeater to the east. But to the northwest, I had no trouble bringing up even the Columbia University repeater most days.

Since I'm new here, I'm not quite sure where Kingston is yet, but I'm quickly getting used to the fact that what I considered a LONG DRIVE in the St. Louis area, is just a SHORT HOP to the store here, hi hi.....
We'll have to get together for an eyeball one of these days!
I missed the local hamfest which I really wanted to attend and get to meet some faces.
Perhaps you can tell me where the local CANDY STORE is around these parts. That's part of the reason I'm not up and running yet! Need STUFF to get everything back up and on the air.

I enjoyed CW for umpteen years, it was my favorite! But then along come distractions (rug rats) and limited time and I finally switched over to voice where I could skedaddle quickly if need be.
I'm semi-retired, but often keep so busy, I wonder how I ever had time to work in the first place.

Plus, I didn't know if where I was living would be temporary or permanent. As of last friday I know it will be permanent, we bought the place! So, now I hope to get set up before winter, but there are many other more pressing issues to take care of now that we know we will be permanent residents at this location here in south Knoxville.

I have just completed at least 50 hours of modelling a coil where an assembly was made of half coils and the relative positions of such were altered by raising or lowering the half coils which thus introduced vertical connecting pieces between the half coils. In addition to the above the half coils were wound CW and CCW in turn This arrangement was fed at the bottom in vertical style.
Unlike other modelling I took great care to ensure max use of segments together with the use of computor variable dimensions when seeking max radiation,impedance and all that.
What I found was as follows:
The phases of the current stayed relatively constant EXCEPT it consisted of two phases opposing each other.
The manipulation of the coil positions retarded rapid changes in impedance (I see this as a consequence of reducing reactive components that one has with a normal
coiled load)
No matter what changes I made(I never changed the diameter of the coil but did change the diameter of the coil wire e.t.c) I was never able to obtain characteristics of a normal whip.
From the above one can deduce that removal of reactance from a structure brings it closer to a dummy load.
On the question that I was fussing about i.e. dust generated as a dust cloud in straight and curved travel
represents losses per Newtons law of action and reaction.
the dust portraying the reactive forces to radiation.
So I found out for myself what everybody already had accepted as fact. So now another silly question which I only pose to myself..Interchange of energy between reactances are understood but what does overshoot of energy between reactances do, create heat or radiation?
The energy held by the overshoot is now of opposite phase to its original destination !
No I am not starting another thread, just explaining the modeling that I did in my relearning proces for all to share.

Hello Gary,

I guess the best components store around here would be Shields. I'm pretty sure they have a web site. I usually order whatever I need from Mouser.

Kingston is about 20 miles west of Knoxville on I-40. Welcome to East TN, congrats on the acquisition, and I hope you have a high tolerance for orange. The locals get a little carried away with that around this time of year. I am originally from this area, but I have spent a lot of time living elsewhere. I guess I liked Memphis and KY best.

The Sevierville hamfest used to be (and may still be) one of the first ones of the year, and it was a pretty good one. Oak Ridge or Clinton also has a nice one. I believe Knoxville has a couple each year. I try to go to them when I am not working, but I work a really strange schedule. I imagine e-Bay has had a major impact on the hamfest business. I have been looking there for 222 MHz equipment with the idea of getting into meteor scatter on that band. I started out with an old TS-711 and an eleven element beam my dad got from Army Mars years ago and discovered high speed CW and meteor scatter, and things sort of grew from there. I now run a TS-2000X and deliver 1.5KW to four 9 element elevating yagis on 2 meters. I picked up my current callsign when I decided to get into EME since WB4KMH would be a bit much to use in such a difficult undertaking.

I hope you enjoy your time here in East TN. The weather usually isn't too harsh, and the mountains are very colorful in the fall. Hope we hear you on the air soon.

I noticed ALF Enterprises is selling the Yo-Yo-Tenna line of portable dipole antennas recently featured in QST, Worldradio, CQ, etc. at a little bit cheaper price and cheaper s&h than noted at the mfg's website. Being that most of us hams are frugal, I'd thought I'd spread the word. Here is that long webpage URL:

http://www.alfenterprises.com/amateur_radio/accessories/amateurbaseantennas.htm

You need only two tools: WD-40 and duct tape.
If it doesn't move and it should, use WD-40.
If it moves and shouldn't, use the duct tape.

"If anyone cares to discuss the subject, or, explain how the conductor laid on the ground can lose its conductivity, bring it on."

My observations on Tom, W8Ji`s antics are similar to Yuri`s. Too bad because Tom has much to offer. We all make mistakes, and for everyone`s benefit we should admit we are wrong when it happens.

The loss from an r-f conductor near the earth is likely more from displacement (dielectric) loss than conductor conductivity. At Radio Free Europe we found it more economical to build a kneehigh 2-wire 600-ohm transmission line of Copperweld than to build a stainless steel dissipation lline high above the ground to dissipate 50 KW. It worked very well but it was a collision hazard.

What did he say that was wrong ?
What book this time are you quoting from?
What book states that you are correct in your own analysis?
We all know that you have some sort of connection with Radio Free Europe so
how did your antics prove
that Tom is in error? Yes Tom and others including myself can be
fraustrating but is that justification for dragging him thru the mud? Your
post sounds like a "swift boat"
advertisement so maybe some of it will stick

2385. Copper Clear Coating Options

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-25 22:57:43 UTC
From: Drink <drink@gnt.net>
Message-ID: <cgj5dnnek1@news.utelfla.com>
Source record: 90406

Hi All,
I recently made a Moxon rectangle for 2 meters and used 1/2 inch copper tubing for the elements. When finished, I polished the tubing and coated it with a clear coat acrylic. It's a true work of art with shiny copper, stained oak and brass screws for fixing but the acrylic is so brittle that I can simply scrape it off with my thumb nail.
Is there another clear coat I can use that will be much stronger? Polyurethane? Some form of epoxy? Or, does acrylic have some property that doesn't affect/interfere/interact with RF?
Best Regards,
Jim, WP3JQ

>
> Roy Lewallen, W7EL

You are correct - as usual - so - if the transmission line (up to the point
of connection to that conglomeration) was carrying a balanced current (
equal in voltage and opposite in polarity at corresponding points) - then
the aforementioned line could continue to assist with the migration of
electrons along the path of conductance in a balanced manner.
;-)
that's why a half-wave of coax can be used at a particular freq as a 4-to-1
balun - where the braid is 'left behind' but the current continues with the
voltage doubled - thus quadrupling the impedence matching ability... ...
and all that stuff

2388. ANTENNA TWINLEAD FEEDER

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-25 23:44:36 UTC
From: folio <ve2lxNOSPAM@sympatico.ca>
Message-ID: <Fv9Xc.22349$DG.1106859@news20.bellglobal.com>
Source record: 90409

hello to all
from Gilles ve2lx

1 st past ever on this group

I just install temporary an invert dipole feeded with tv twinlead 300 ohm

actually I have no RF interferences from 160 to 12 m (but only low on 10 m but no more usable anyway) compare to my end fed I had 2 month ago...!

antenna length is 66 ft or 33 ft each side and feeder length about 48 ft...the dipole is parralele to the back of the 20 appartement's house and the full SFC remote coupler or tuner (builted only for wire tuning) is on my back galery 8 ft from radio on 3 rd floor a little above hand rail...!

(((......I found 75 ohm twin lead......)))

and (I would like to use it instead) for10 to 80 and 160 m (actually I do it with 300 ohm twin lead accepting low efficiency on 160 m and perhaps on 80 m but it is ok.

my target
1...is to have as much efficiency as I can for all bands use primaly on 40 and 20 m (reason for 66 ft)
2...at 75 ohm on 80 meter there will be much less SWR (like 1/30: OR MORE WITH 300 OHM on 80 m) due to unmatch compare to 300 ohm
3...there will be better energy transfer because dipole is + or - 75 ohms and feeder also and the tuner will search less value to match then therefore les chance of RF problem radiations form feeder (les larger) and so on
4...feeder length will have less effect at 75 ohm on a all bands consideration...?

is this thinking correct

wishing to ear from amateurs with good experience with balance or twin lead feeder

>
> Jerry

and as Roy pointed out in the other thread - the assembly will just
facilitate the transmission of a balanced load - not 'cause it' to be
balanced -
But as you pointed out - using such an assembly aids in impedence matching
schemes - and if the line happens to be balanced - it won't tip over . ;-)

This is interesting. Are the negative effects due to the fact that induced magnetism will persist, and thus set up additional impedence on the line ? and does this skin effect caused by the magnetism vary significantly with frequency ?

Try relatively clear ship's varnish or what is sold as such. It's designed
for harsh weather protection and has no effect on antenna performance. I
have used the stuff on copper magloops. Keeps a nice appearance for ages.

I really do not know Hal as it all was a surprise to me.
I wanted to believe that the lack of phase change would keep radiation at a peak without thinking of a possible constant weak radiation. It also surprised me that there appeared no current curve that one associates with a whip which makes one wonder about the cancellation of reactances along a radiator and leaving just resistance.
Proff Underhill stated last month in RADCOM (U.K.) that a lot about loops is unknown which I find obvious as some in this group view mutual coupling as following the same rules of very close coupling not realising that the inductance inside a coil is a world of difference to that from coupling outside of the coil. One esteemed member of this group stated that there is no mechanical pump type thing in radiation when I pointed out the function of a loop/phase change action in the combination loop dipole arrangement. I sure hope that the experimentors of tomorrow are not discouraged by those who are prisoners of yesterday

Dear Richard,

The Radio Shack manual linked below, which I have, and came with the antenna, doesn't mention twiaxial cable because no twinaxial cable with an impedance of 75 ohms is available at a reasonable price, so people use 75 ohm cable because it's cheaper. If I could get 75 ohm twinaxial cable I'd use it.

The impedance of this and every open dipole antenna is around 75 ohms, one quarter of the impedance of a 300 ohm folded dipole, just about ten percent from the impedance of empty space. We are in an atmosphere....

However, the OEM antenna is a flexible _open_ dipole with a characterstic impedance of 75 ohms. I think 100 ohm twinax is a good choice.

Can any readers source 75 ohm twinax?

Doug

Hal Rosser wrote:

> This is interesting. Are the negative effects due to the fact that induced
> magnetism will persist, and thus set up additional impedence on the line ?

Not if I understand you correctly. The effect I'm describing isn't an impedance due to inductance, as you seem to imply. It's that the density of an AC current decays exponentially from the surface downward into a conductor, increasing the resistance of that conductor (known as skin effect). The skin depth is a measure of how rapidly it decays and therefore how resistive a conductor will be, and the skin depth is a function of the frequency, the DC conductivity of the material, and its permeability. I'm sorry I'm not able to explain why increased permeability decreases the skin depth except that it's due to the increased magnetic field opposing current into the conductor (which might be what you tried to say). I'm sure you can find a lot about skin effect on the web, as well as in any electromagnetics text.

> and does this skin effect caused by the magnetism vary significantly with
> frequency ?

I honestly don't know the answer to this. The permeability of ferromagnetic materials does vary with frequency, in what appears to be an unpredictable way. Whether this value or the DC permeability should be used for calculation, I don't know. I suspect that the DC permeability should be used, and the permeability change with frequency regarded as a change in effective permeability -- but I don't know for sure. I'd really appreciate it if anyone who does know would comment. Of course, skin depth varies with frequency even if the permeability is constant.

Source record: 90325

Hi Group,

I am starting to see the RCA's direct TV disk showing up for a fair price at garage sales. I have picked up about 3 of them so far.

What I have learned on the internet is that the sates are around 12GHz and the down conversion is about 1 GHz.

I recall a ham band around 10GHz and wander if anyone is doing work with them on the ham bands?

How much gain would this antenna get at 12GHz. I believe the diameter is about 19 or so inches.

Thanks!

Recently Tom argued with Yuri that loading coils must have the same current in and out. Circuit theory does not directly apply in all cases due to the possibility of a reflected wave on the coil and due to radiation from a loading coil.

Did Tom ever admit that it`s possible that current into one end of the coil does not necessarily equal the current at its other end?

Shape has a very minor effect on the radiation resistance. Shortened 1/2
wave loops have a radiation resistance typically in the 10-12 Ohm region.
The halo has an elliptical (about 3dB out of "omni") and care must be taken
to choke off radiation currents on the feedline and support mast.

I haven't seen a posting from Tom on this newsgroup for a very long time.
Did you confront him to his face about this or are you talking about him in
his absence?
Go to EHAM and confront him like a man especially if this original
confrontation
occured else where. Ifyou have a problem with some one about something then
talk to him directly
instead of throwing mud when he isn't looking. There have been many
statements made about Tom lately
that I can't verify in RRAA records so why are you bringing mud to this
table especially
when the target is not here to defend himself and especially if your
charges are scurrilous
and without depth

2412. Stainless steel antenna wire

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-26 04:58:14 UTC
From: Larry Benko <xxw0qe@comcast.net>
Message-ID: <CvCdncgWXJp18LDcRVn-iw@comcast.com>
Source record: 90333

Since this topic has been recently discussed, I was wondering how well EZNEC (ver. 4+ here) would model a wire antenna made with stainless steel wire. The "Wire Loss" table in EZNEC allows a User Defined Resistivity and Relative Permeability. Would the fact that SS wire is usually comprised of a very large number of strands has any appreciable effect on the loss? Assuming that EZNEC can do the modeling correctly, what would be approximate values to use for the resistivity and relative permeability? I did a quick measurement in a short piece of SS stranded wire measured a DC resistance (with a 4 wire ohmmeter) of ~50 times that of copper.

Thanks and 73,
Larry Benko, W0QE

Source record: 90334

I have a great deal of respect for Tom, W8JI. In fact, there are few people I respect as much. I regard him as being exceptionally honest, very analytical, and always seeking to find the truth and increase his knowledge. Whenever his view of how things work have been shown to be wrong, I've found him to readily accept the corrected view, and be grateful of the opportunity to learn something new. I've also learned from him on more than one occasion. One notable case is the idea of using a balun at the input of a tuner to improve the balun's balancing properties. I had believed it to work, but he showed me where I was wrong, giving me the opportunity to increase my knowledge.

I find it contemptable and cowardly to attack him -- or anyone -- in a forum where he's not a participant and isn't present to correct misquotes, quotes taken out of context, and otherwise respond and defend himself. People doing so should instead sign onto one of the election campaigns or go on AM talk radio, where such gutless, dishonest, and mean-spirited activity is the accepted norm.

I believe the Russians have a word for this kind of cowardly and "uncultured" activity -- something like "nyekulturny". Maybe Yuri knows.

Roy Lewallen wrote:
> Do you have a quote showing exactly what Tom said, in context?

Here's one from his web page:

"What determines current distribution in a loading coil? The capacitance
to the outside world and the impedance above the loading coil. The current
in any inductor would be equal at each end except for displacement currents,
which are "imaginary currents" that flow through capacitance."

He completely ignores the fact that, for a standing-wave antenna, the net
current is the superposed phasor sum of the forward current and reflected
current and whatever phase shift occurs through the coil is doubled because
those two currents are traveling in opposite directions.

He is thinking lumped circuit model when he should be using a distributed
network model. What he says is reasonably accurate for a traveling-wave
antenna but certainly not for a standing-wave antenna.

EZNEC clearly illustrates the difference in the currents when the coil is
modeled as a coil of wire segments and not as a lumped inductor. Anyone who
would like a copy of the EZNEC file need only request it.

Hi Larry,

Below, you show you have a Kelvin Bridge capable of determining the
resistance regardless of stranding, trust your tools but know their
(and your own) limitations. Multiple strands is an asset at very low
frequencies for Litz wire - an unlikely application in this forum
(given both that stranded wire does not meet the criteria for Litz
wire, nor do the operating frequencies we typically encounter here).

> Assuming that EZNEC can do the modeling correctly,
>what would be approximate values to use for the resistivity and relative
>permeability?

Only you are in a position to determine its ferromagnetic
characteristic, at least to a first pass (of the magnet)
approximation.

> I did a quick measurement in a short piece of SS stranded
>wire measured a DC resistance (with a 4 wire ohmmeter) of ~50 times that
>of copper.

Seems like a suitable clue. It could be a greater problem if you
built it into coils, although it may enhance the antenna's efficiency
per unit length through circular radiation endowed by powerless
acceleration in counter-anti-clockwise constant simultaneous phase
changes.

>SS stranded wire measured a DC resistance (with a 4 wire ohmmeter) of
>~50 times that of copper.

Stranded wire will increase the RF resistance compared to the equivalent cross-section of solid - but a DC resistance measurement will not show this.

In both cases the skin effect forces the RF current to flow on the surface. The solid wire has a continuous surface, but on stranded wire the current path has to hop from strand to strand. Because the sideways contact pressure between strands on the surface is not very great, this increases the resistance per unit length.

Bare stranded copper is very vulnerable to this effect, because copper corrodes readily in the atmosphere and even a thin film of corrosion will force the strands apart. You'd be very unlikely to notice the gradual worsening of performance in something like an HF antenna... but it's still there.

Stainless steel is rather an opposite case: the RF resistance of most grades of SS is so high that stranding may not make much extra difference, and of course it's also much less easily corroded than copper.

What kind of wire you choose depends on your priorities. For example, for marine use the absolute priority is that the antenna is available at all times, so they use thick stranded phosphor-bronze for their HF "wires". It isn't the best RF material, but it's so strong, your 80m and 40m inverted-Vs make very good tower guys.

Group..I've just discovered this group (what took me so long?) and am impressed with the knowledge here. I am shopping for an antenna analyzer and am stymied by the choices (or lack thereof). In all of hamdom (sub $600), I only find MFJ, Autek, AEA wireless, and Kuranishi to choose from. I've checked eham reviews and found that the AEA VIA (not Bravo) rates highest...and most expensive. Probably worth it. Unfortunately, it's only good to 54Mhz, and I'd need up to 450Mhz. I know this is impossible, and would be willing to go with separate units (Autek), but they have awful reviews re: quality.

My question: What are you guys using for HF measurements? What about V/UHF measurements? Do you recommend any particular model? How about used HP gear from ebay (yes, I know the risks). V/UHF is my priority since I'm building some copper loops for 6 and 2. What say you sage antenna gurus?

Hi Darrell
guru, schmuru
you will find the gamut of experience and education here, though
as well as some amazing flame wars
I have the MFJ with 450 and it works OK
Only measures SWR on 450.
It's not a laboratory instrument, but I have used it for years and it gets
the job done.
Priceless for setting up the HF mobile.
I have no comparative experience except with an old General Radio bridge in
my AM radio days decades ago.

The link brings up fond memories of a very similar debacle I saw first hand. This one wasn't "engineered" by a home shop canoe builder, this one was put together by none other than the U.S. Navy.

My first job out of school 40+ years ago was as a civilian mechanical engineer with the U.S. Naval Air Engineering Center. The group I worked in was responsible for the design and ongoing development of carrier-based steam aircraft catapults.

Catapults are individually calibrated and periodically recalibrated by launching minimum-budget wheeled vehicles of various weights called "deadloads" off the catapults in into the water when the carrier is in port. The idea is/was to create weight vs. end speed vs. steam pressure curves which are vital bits of info when twisting the catapult steam pressure control knobs below to get the airplanes off the end of the catapults flying nicely instead of into the drink or on the other end of the scale not torn apart by excessive g forces.

Deadloads are, or were at least back then, simply big steel boxes of various weights to simulate the range of aircraft weights the

catapults dealt with. Each corner of the box was equipped with a wheel salvaged from junk aircraft. They were divided up into internal "watertight" compartments and hopefully they floated after a test shot and could be reused. Some deadloads floated, some leaked or came apart and sank. An average deadload weighed 35,000 pounds and was launched at perhaps 115 mph.

Along came this self-proclaimed engineering genius from the next group yonder who decided that his route to military fame and glory was to become the guy who came up with the concept of filling the deadloads with foamed flotation compounds and save all deadloads from the briny deep.

At that point in time DIY foamed flotation plastics were experimental and were not yet on the general market. But he managed to acquire some samples of a two-part foaming compound for test purposes. He also managed to get hold of an old deadload and parked it on the tarmac off to the side of the main hanger and went to work drilling holes in all the compartments. Then he went back and poured carefully measured amounts of part 1 and 2 into each compartment.

I had no idea what was going on out back at the hanger, I wasn't involved in it. Until a lieutenant commander who worked in our area came down the main aisle with tears of laughter rolling down his cheeks hollering "You gotta see it to believe it!" So off we trooped to find out what was going on. The genius had slipped a decimal point with his slide rule and the deadload had been loaded with ten times more foaming agent than it should have had.

The deadload had turned into a steel ball 10-12 feet in diameter with it wheels neatly arranged around it's equator, plastic shoots were flying dozens of feet into the air like fireworks and all over the tarmac, beyond priceless.

I keep wondering what that guy would have done to a balun box . .

Roy, W7EL wrote:
"Some stainless steels are ferromagnetic, with a permability I`d guess at 100 or more. That reduces the skin depth, and therefore increases the RF resistance by a factor of 10."

Being ferromagnetic does not disqualify an antenna material. Most CB whips are stainless steel. They aren`t too lossy because they are only about 1/4-wave at 27 MHz and must be large enough in diameter to be durable. In the range of 0.55 MHz to 1.7 MHz, most transmission is from ordinary non-stainless steel towers. The only coating on many of these is paint. The cross-section to length ratio is economically small, but I doubt the loss added by using nonplated steel could be measured.

Best regards, Richard Harrison, KB5WZI

I just got down from the scary-as-hell trip up the tower. The wind was really blowing up on top. I stripped the old stuff and will have to go back once I figure out what is need. The 3 foot (~2 foot past the tower) wooden stand off I used last time was pretty wx-worn. I don't think PVC is strong enough and the sun eats the the PVC stuff up. May have to use a good hard wood again. It will probably out last me. Still not sure how to secure the Inverted-L antenna wire to the stand off on top. It needs to be tied off so it will not slip at the bend.

I am getting too old to climb a 22+ year old tower. Everything looked okay...I just wanted to get down.

Whoa... now you are misquoting Roy.

He never did DISQUALIFY the use of stainless steel
He clearly stated in technical terms what stainless steel
lacked in an area that is important with respect to radiation.
I suspect the use of stainless steel for consumer antennas
is an engineering one to prevent rust and antenna mechanical distortion
which outways the loss in efficiency.
It was this difference that Roy was alluding to and is the reason why
amateurs take note of the characteristics of material used and is why
aluminum,copper and the like
is used in the communication world. Many in the amateur community allude to
communication obtained with a wet string but in no way are they
DISQUALIFYING the use of aluminum and the like. Stop throwing mud and get
with the program. You will never,ever make the smallest piece of your mud
stick to the likes of Roy and Tom with mis quotations.

I've used old broken hockey stick handles for standoffs. They will last
for years and are are very strong. The handle never breaks, it's always the
part at the bottom.

Yes, and W1GHZ has an on-line book about using them as 10ghz antennas:

http://www.qsl.net/n1bwt/contents.htm

In the Twin Cities MN area we have nearly 2 dozen people on 10ghz, most with
various types of DSS dishes. If you got the feed horn with the dish, you can
sometimes drill it out to 3/4" for 10ghz.

>How much gain would this antenna get at 12GHz. I believe the diameter is about
>19 or so inches.

At 10ghz we typicly get in the area of 31-33dBi gain from the 19" dishes.

Hi Phil

Thanks for the name of the Candy Store!

Besides the killer orange, I live very close to the War Zone where the touchdown BOMBINGS take place, hi hi.....
Thought I was back in Nam until I was told what it was!

My step son is going to school in Memphis, so far he has had one car stolen, two destroyed beyond FMV by vandals and theives. Far cry from what it was years ago when I stayed there for a few months.

Of all the years I have been a ham, I never got into to many of what could be the interesting parts of it. When I first started, all the locals were on 6 meter AM, my rig was a used Heathkit Sixer (Lunchbox), just sold it before moving down here to Knoxville, along with most of my Heathkit gear.
My first 40/80 CW transmitter was a home brew job and I used it for years. Using a Heath HR10B for the receiver. I finally built an HW-101 in the early 70's and used it for over 20 years.
It was when I finally burned out on CW that I found the need to upgrade to something that handled voice a whole lot better. So I purchased a used 830-S and have been using it ever since.
Plus the array of HT's and old equipment I would keep barely working. I really hated to let almost everything go, but you just can move 20 years of accumulated junk very easily. I still had 7 trailer loads when I moved south, but that included one small business I retained too.

I will probably live out the rest of my days here! It's nice country now and will probably shift in the area I'm in downward, but I can hope for the best. I can't visualize having to move again, hi hi.....

I do hope to get back on the air before winter sets in! I finally made life member status at our local repeater club (no more dues, hi hi) Then I up and move! Figures.

>

Hi All,

I've repeated the models with longer runs: 1000 meters length @ 80M.

For transmits, the single wire over ground shows a gain of 0.42dBi at
10ï¿½ but with a F/B of 16.4dB. EZNEC proclaims the model exhibits 17dB
loss.

For transmits, the double wire over ground shows a gain of 1.2dBi at
10ï¿½ but with a F/B of 11.7dB. EZNEC proclaims the model exhibits 17dB
loss.

However, Beverages are not typically the first choice for
transmission, but rather reception. Does reciprocity hold? As no one
has offered to help the Little Red Hen, would they care to share in
the cake?

For the receive single wire Beverage @ 10ï¿½ w/600 Ohm load
Total load power = 5.543E-07 watts

For the receive double wire Beverage @ 10ï¿½ w/600 Ohm load
Total load power = 6.623E-07 watts

Now, if we compare the two receive loads we find they differ by .77dB
which is the same difference for the transmission models. By most
accounts, that means reciprocity prevails. By further accounts, that
means the double wire system is superior - if you want to lay out 1000
meters of wire for less than one dB (that pesky one dB value judgment
again).

By this point, what with all the trolling going on and so little
actual technical content, What was this all about?

Hi Darrell,

I was just about to tell you what I use, but Richard, above, beat me to it. For HF measurements this bridge, the General Radio 1606-A, is the Cadillac of all bridges. It 's been the bridge of choice for nearly every AM broadcast engineer in determining t he impedance of AM broadcast antennas since it came on the market in 1955. It's very nearly the same as it's predecessor, the GR 916-A, which came out in the 1940's. It's what the AM antenna engineers used prior to the 1606.

You can find the 1606-A on eBay, and the price ranges from $200 to $1000. However, you also need a signal generator to feed it the signal it needs to operate, plus your receiver as the signal detector.

I also use more modern impedance measuring devices, such as Hewlett-Packard's HP-4815 Vector Impedance Meter, and their HP 8405 Vector Voltmeter. These two instruments are also laboratory grade quality. All of these instruments far exceed the accuracy of the devices you listed.

Hope this helps,

Walt, W2DU

Hi Reg,

I obtained my 1606-A in 1968, Ser # 924, directly after calibrated to IMS. I have checked it periodically against some of my own standards, only to find the calibration hasn't varied even the width of an engraved graduation mark on either the reactance or resistance dial in all these years.

Hi Punchinello,

Your hedged question belies an ignorance of premium equipment that has
been dominant in the field for 50 years. How is it you fail to
recommend what you use?

I have calibrated such in a Primary Electronic Standards Lab against
standards traceable to NBS at the time. [but you knew this already]
I did such work under contracts to Boeing, and the model I own was
acquired from Boeing complete with certificates of traceability(not my
own work, I have only on occasion found a piece of precision gear with
my stickers on it).

I have never encountered a GR 1606 that fell outside of its
specifications - except for one where someone apparently burnt out one
bridge component, a resistor. Undoubtedly this was accomplished by
applying a transmitter to the excitation port - one can only imagine
the fate of equipment connected to the detector port. This was very
simple to recover from (one resistor). The instrument is robust and
built like a Swiss precision watch. There are very few things that
could go wrong and only under physical duress (like dropping it down
three floors of stairs).

You're correct that CB whips, 2 meter whips, AM broadcast towers, and the like are just fine because of their large diameter.

But think about it a little bit. If you reduce the frequency by a factor of two, the length of a resonant antenna increases by a factor of two. The skin depth decreases by a factor of the square root of two, so the resistance per unit length increases by this factor. So at half the frequency, the resistance of a resonant antenna has increased by the square root of two. Furthermore, you don't typically use 1/4 inch diameter wire for an HF dipole, for example. (And most hams presumably wouldn't make an HF dipole from surplus broadcast towers -- but then I haven't seen your station.) Assuming you're using a resonant antenna of constant diameter, the loss gets higher as the frequency gets lower.

Now go back and read what I wrote. Notice that I said that the wire was most likely to be a problem with antennas on the order of an 80 meter dipole length. Now you understand (I hope) why that qualification.

If you use an antenna at a frequency higher than its primary resonance (such as a 40 meter dipole on 15, or a G5RV on a high frequency band), the loss gets greater yet, since the skin depth decreases with frequency.

I have an MFJ 269 and a GR 1606A. Each has its place.

At my location, about 10-15 miles from a hilltop with powerful TV, FM, and I believe AM broadcast transmitters, the MFJ is pretty useless for most antenna measurements. The impinging RF confuses it. It's great for fiddling with circuits on the bench, quick measurements of coax length, and checking the resonance of a 2 meter whip. I'm sure the RF problem would be the same for the other analyzers. Years ago, I rented an HP vector impedance meter for a consulting job, and it too was unable to handle the RF environment. A friend lent me an ancient tube-type Z meter that had a tunable detector, and I ended up making the measurements with it. (That was before I got the 1606A.)

I use the 1606A when I need to make serious and accurate antenna measurements. It's tedious to use, having to be calibrated at the measurement frequency before making measurements. It only goes up to 60 MHz. And it requires an external signal generator and detector. The external detector is really its strength, though, since by using a narrowband detector (I use an old ICOM R1 portable receiver) I can make good measurements in the RF environment I live in. It would be a real nuisance to haul it up a tower, although you can put it on top of a stepladder.

Sorry, I haven't used any of the other analyzers so can't help you out with the comparison between them.

It's gratifying to learn that the 'ole 1606 is still being used by people in the group. About ten years ago I wondered what I'd do if anything happened to mine, especially since General Radio was already out of business, so I found a 1606-B for $400 as a backup. Son Rick, WB4GNR, is using it, but it's still my backup.

> My question: What are you guys using for HF measurements?

The original Autek. Limited accuracy,
but *very* portable and very useful.

I'm building the N2PK Vector Network
Analyzer, which is only good to 60Mhz,
with laboratory accuracy. Paul has hinted
at extensions to allow se to 450Mhz.
See www.n2pk.com .

The GR bridges suggested are very good,
but not too portable.

Me too. Well, let me rephrase... I have had the kit ($220) for about
8 months and have yet to start on it ;)

First I figured I needed a better, smaller soldering iron. $100.

Then I got that and realized I can't see the parts. Got a 10X
Optivisor. $35.

Depth of field is really marginal. Got a lighted magnifier. $50.

Ready to go... oops no anti-static mat and right in the middle of
building bathroom vanity cabinet. Figured I could save money by DIY.

New Delta Unisaw. $1500. Dovetail jig. $400. Better lighting in
garage $400. Hardwood $400. Misc router bits, finishing materials,
spray gun, screws, door and drawer hardware and my labor at $0.05/
hour... don't ask.

Other than that, I use a Boonton 250 or an HP 8405 for impedance
measurements.

That's fine, you are entitled to your opinion. I am sure Tom has also respect for you (as I do) and he would think twice of pontificating at you than at someone who is not so vocal or "famous" due to their status or postings on Internet.
My experience is, as I mentioned it before (I don't take crap for anybody) that when I brought some correction to his fallacy or presented idea that did not exactly jive with his "knowledge", he would in first posting come on the high horse and pontificate and ridicule the person, rather than engage in the discussion of pro or con and try to sort things out. That's what pisses me off, when someone who is wrong resorts to personal attacks (like democrats) rather than engaging in substantive discussion.
He thrives on reflectors where he is protected by the administrators that worship him and will not allow discussions when he is on the losing side. He is not on Amp reflector, mainly because R. Measures debunked some of his postings proclaiming fallacies. Same was on TowerTalk with K7GCO, who called him "great technical imposter". Been there, was done to me.
Again his modus operandi is, when he is wrong, he attacks person rather than engages in discussion and admitting wrong. Then goes quiet for few months and later corrected, emerges as a "guru" on the subject, like it is his own idea. Never admitting or giving credit where is due.
I had about 6 situations like that with him, records are at the web sites, anyone can look it up. I don't give a hoot about "reputation" among the hams, I have a life outside of ham "world". It just burns me when I try with good intentions to bring correction to some crap that is floating around, and for it I get personally attacked and ridiculed.
I don't give a hoot who people want to worship, I have my God. I try to point out some errors or problems, be it wrong information or crapy equipment.
If you want to find out who is gutless, dishonest and nyekulturny, go back to some archives, I can supply you subjects and see for yourself.
I learned thing or two from Tom too, but I also see lot of textbook stuff on his pages and even there are some misleading information. But I will not take crap for saying that 2 + 2 = 4 is wrong.

>
>I find it contemptable and cowardly to attack him -- or anyone -- in a

>himself.
>

The last thing is sentence about wire "losing" conductivity by laying on the ground. That's what I brought up. I know what was the situation with dual wire Beverages, but that sentence was wrong way to describe what is happening in the system. If he is so smart, he should be more careful when describing technical matters. Words mean things.

BTW Tom used EZnec to "prove" that current across the loading coil in the loaded antenna is the same at both ends. When you replace that coil with same inductance value loading stub, you find that current is (significantly) different at the ends of the stub.
Have you corrected him how to use EZnec properly to model lumped inductance and get results that jive with reality? Cecil showed and explained the stuff. In his presentation at Dayton, Tom still propagated that nonsense.

Anyway, back to DR1, getting tired of arguing with "experts".

Hi Darrell,

I have used the Autek VA1 and the MFJ 259B here in 9V for about a year. Must have gotten a good Autek as it has performed well. All of the MFJ series I have used in the past and they will do the job but as has been said, high RF enviornments render it useless.

The MFJ that goes to UHF we used on a field day trip to a remote island just off 9V and it also did a good job. YMMV but the VA1 goes into a pocket for a tower climb, is a bit fiddley, but I find I use it more than the MFJ.

The analyzer post gave me an idea you may want to try out -
take equal pieces of copper and stainless wire -
Long enough so that an antenna that size would fall within capabilities of
the analyzer -
see what the ol'analyzer tells you about resonant freq for each -and
resistance for each at resonance -
then try again at different lengths and freqs - compare results
then there oughta be a publishable ratio for those freqs. - whatcha think?
please report back within the week ;-)

I dunno about the exact measurements - but I used 300-ohm belden twinlead
(the kind with copper-clad-steel conductor) as a feeder - but tried to keep
to the G5RV measurements - and had good luck with it.

if you're using them as couplings -y' might try looking at pvc pipe -or -
use fiberglass cloth and resin and 'roll your own'.
I thought about using resin (with hardener)- then soaking a layer or 2 of
newspapers with it - then rolling my own quad spreaders - but never got a
round 'tuit' - but its on my list of experiments to try.

I assume, possibly incorrectly, that it is a VHF/UHF scanner. It would
be much simpler to build a discone -- even just a skeleton discone would
probably do the trick.

Well, you're right that the group's dedicated to ham radio-type antennas
but I'll still give a try. Don't know how many floors up to your roof but,
at 43 plus floors, you'd get awesome reception I suspect if you just put a
real antenna on the roof and ran the line down to your office. You might
not even need a fancy one like winegard makes or any other beam antenna
readily available at Radio Shack. Take a look at 1) where the TV station is
that you're looking for and 2) how far away it is. Now, compare that to how
acceptable the reception is with your rabbit ears is. Take a look at this
website.
http://www.starkelectronic.com/allant.htm
They make some good omnidirectional antennas for your application with a
preamplifier. That might do the trick. Make sure you do your own research
based on your particulars that I'm not aware of. Better yet, give 'em a
call. They're experts on this one:).
Best Regards,
Jim,WP3JQ

Yuri, K3BU wrote:
"If anybody cares to discuss the subject, or explain how the conductor laid on the ground can lose its conductivity, bring it on."

"Lose its conductivity" is likely a mischaracterization.

Conductivity of a wire at a particular temperature and frequency is a function of the form, size, and material the wire is made of.

Proximity of the earth should not affect conductivity directly.

Loss from an R-F carrying conductor can come from energy coupled into the surroundings. Obvious source is the R-F in the conductor. Closer the conductor comes to the earth, the higher its capacitive coupling, and the more current flows in the lossy earth, especially in the case of an unbalanced conductor.

The fact that a conductor laid on the ground can lose R-F does not mean it lost conductivity. It means the conductor has induced loss in the ground upon which it is laid.

Best regards, Richard Harrison, KB5WZI

Quoting Kraus: "A coil can also act as a 180 degree phase
shifter ..." Exactly how does a coil act as a 180 degree
phase shifter if charge cannot travel in two directions?
Seems that you also don't comprehend the nature of a
distributed network such as a bugcatcher loading coil.

> For a guy who doesn't seem to be able to make the distinction,
> you don't have any business criticizing Tom Rauch's understanding of
> the situation.

So you believe that charge density is constant throughout
an RF distributed network?

I'm going to add this to my web page. It's a mobile antenna with an 4'
bottom section, a loading coil, and an 4' whip. The loading coil is
made up of EZNEC segments with an octal shape. It is 4.5 turns in 0.9
foot length and one foot diameter. The feedpoint current is 1 amp.
The current in the first segment at the bottom of the coil is
0.9956 amps. The current in the last segment at the top of the the
coil is 0.5326 amps. The number of electrical degrees that the coil
occupies is about 50 degrees, more than half of the 90 degree antenna.

You could do worse than a 1/4 wave groundplane for approx 160 MHz. It will be 3/4 wave on 480 MHz as well and thus reasonably efficient.

Original W8JI post:
<"The only thing that prevents people from shooting themselves
in the foot with the wire below the Beverage is the wire
couples to the lossy media below it so well it becomes very
lossy, and of course that means it doesn't help with
stability or termination.">

>Yuri, K3BU wrote:
>"If anybody cares to discuss the subject, or explain how the conductor
>laid on the ground can lose its conductivity, bring it on."
>
>"Lose its conductivity" is likely a mischaracterization.

"Becomes very lossy" or paraphrased "lose its conductivity" to make the point?

>Conductivity of a wire at a particular temperature and frequency is a
>function of the form, size, and material the wire is made of.

QSL.

>Proximity of the earth should not affect conductivity directly.

QSL

>Loss from an R-F carrying conductor can come from energy coupled into
>the surroundings. Obvious source is the R-F in the conductor. Closer the
>conductor comes to the earth, the higher its capacitive coupling, and
>the more current flows in the lossy earth, especially in the case of an
>unbalanced conductor.

I can see conductor (assuming insulated wire) having its electrical length
affected by the capacitance between wire and earth, but wouldn't current stay
close to same along the length? So, like if we have a coax, which has quite a
capacitive coupling between the center conductor and shield, we would lose
(significant) RF current at the other end?

>The fact that a conductor laid on the ground can lose R-F does not mean
>it lost conductivity. It means the conductor has induced loss in the
>ground upon which it is laid.

(or improved conductivity?)
Isn't it really case of two (resistive) conductors in parallel? Wire and dirt,
with less resistance wire taking over? Why do we use radials if the conductors
become lossy? Why does the Beverage laid on the ground work?
I can see conductor as a (resonant) RF circuit becoming "detuned" and affected
by earth proximity, but saying that it "becomes very lossy" is not very
descriptive. With two wire Beverage I can see the interference between two

"antennas" having same physical length, but different electrical lengths
causing deterioration of pattern (which is observed).

Cecil help? :-)

A charge defined at one point can go one direction or another, Cecil,
as in current, but not two opposing directions at once. And quit telling
me what
I believe; I'll tell you. Let me say in terms you might get this time:
The same infinitesimal charge dQ cannot move in two directions
at the same time. In order to do that it would have to split in two
and that would violate the principle of conservation of charge.

You wouldn't modify a Beverage or any HF receiving antenna to get more gain. The whole object is directivity. If you need more gain, turn up the receiver gain control.

Of course reciprocity prevails. But at HF, the important criteria are different for transmitting and receiving. When transmitting, it's gain; when receiving, it's directivity. The Beverage is poor in the first category but good in the second -- it's a good receiving antenna but a poor transmitting antenna.

Incidentally, Tom W8JI and I worked out a way some time ago to get directivity information from EZNEC. You can see an example at http://www.w8ji.com/receiving_basics.htm in the discussion about Beverages.

If you will note above, there is nothing stated in terms of gain.

>Of course reciprocity prevails. But at HF, the important criteria are
>different for transmitting and receiving. When transmitting, it's gain;

If you will note in the original posting (the content that has been
edited out here) I do employ the term gain - however only as an
informal comparison.

>when receiving, it's directivity. The Beverage is poor in the first

I do not have EZNEC model, but you can read up the thread at
http://lists.contesting.com/archives/html/Topband/2004-08/index.html
and look for 2 wire beverages tec.
Someone tested single wire Beverage and then laid "return" wire underneath on
the ground and noticed deterioration of F/B and higher angle lobes.

Yuri

From: spam.for.the@buerotiger.de
Message-ID: <2p85tpFi44nsU1@uni-berlin.de>
Source record: 90309

Hi there,

For the last couple of years I have been running this 8-band vertical and I have been quite happy with it - so far.

In the last couple of weeks, however, the SWR has gotten worse and worse on several bands, 30, 20, 17 and 15 in particular (1:3 or higher). Since 80 and 40 are absolutely fine in terms of SWR and performance, I supect that /something/ went wrong with the traps of the bands in question (maybe water inside), but I have no idea what to do about it.

The antenna is on top of an appartment building, attached to a chimney with lots of radials for each band. I'd like to get it fixed before the winter season and wonder whether any of you have had similiar problems and what can be done about it.

Source record: 90313

I use a GR 1606A when its capabilities are needed. I even salvaged another from being scraped so I have a back-up.
However, for most tasks, I find that the AEA VIA is the cat's meow. For instance, when trying to tune a Matchbox to strange frequencies, the VIA tells one which way things are going.
I have not tried to use the VIA in the presence of strong broadcast transmitters. At work, we have HP (Agelent) network analyzers and standards to use as comparisons.
AEA also makes, and I use, a modest TDR that is good enough to be used to keep track of transmission lines, connectors, and in-line protection devices.

As Roy, and others, have said: when you need a GR, you need a GR. Before I bought a 1606, I was once loaned the 900 something predecessor to the 1606. This instrument is inside of a small, copper lined suitcase and the particular instrument had been used by the military since about WW2. The outside showed use. It was spot on with my standards and, when I opened up the case, the insides were still bright and shinny. GR made quality instruments.
Though I have not used it, somewhere I have a Delta bridge that was given to me.

Go for the VIA for HF. You will not be disappointed.

Yuri, K3BU wrote:
"I can see conductor (assuming insulated wire) having its electrical length affected by the capacitance between wire and earth, but wouldn`t current stay close to same along the length?"

Depends on distance from the source. Current fades fast close to the source, but at a great distance, the decline is very slow.

Traveling waves don`t require a complete electrical circuit for propagation. They travel well in a complete void. So, the volts and amps far from the wave source don`t need to equal those at the source.

V=frequency times wavelength always prevails. So, capacitance between wire and earth for a given frequency changes the wavelength because the velocity of the wave is changed (slowed) by proximity of the earth.

As a traveling wave is free to be attenuated in travel, current must decline enroute. Brown, Lewis, & Epstein, the 20th Century RCA geniuses, declared that the place to end extending ground radials is where their current becomes insignificant.

Yuri also wrote:
"Why do we use radials if the conductors become lossy?"
Yuri also had answered the question before asking. Didn`t Johnny Carson patent that routine, holding the question envelope to his head while he gave the answer?
Yuti`s answer: "Wire and dirt, with less resistance wire taking over."

Yuri also wrote:
"Why does the Beverage laid on the ground work?"

Kraus says a wave traveling along a perfect conductor produces an electric field perpendicular to the conducting surface, but along the earth the electric field has a forward tilt. The horizontal component of the vertical wave produced by the tilt is associated with that part of the wave that enters the surface and is dissipated as heat. The vertical component of the wave continues to travel along the surface. The emfs induced along the antenna by the horizontal component made of the tilt, all add up in the same phase at the receiver. Maximum response is in the direction of the horizontal wire.

Best regards, Richard Harrison, KB5WZI

Hi Mac,

The predecessor to the GR-1606A was the GR-916A, which was the cadillac of professional bridges prior to the GR-1606A, which came out in 1955. I used the 916A to adjust the tower resistance of WCEN, 1150 kHz, the station I engineered and built in 1948. The National HRO receiver was used as the detector.

Hi Richard,

Interesting you mentioned the Wayne Kerr UHF bridge. In my impedance-measuring arsenal is the Wayne Kerr B108 admittance bridge. The beautiful aspect of this bridge is that it's unknown terminals are balanced, thus allowing direct measurement of balanced lines.

My arsenal also includes: 2 HP 8405 Vector Voltmeters with HP-778D dual directional coupler.
HP-4815 Vector Impedance Meter
GR-1606A
GR-1606B
Boonton 250A Impedance Meter
PRD-219 Complex Reflection Coefficient Meter, 20 to 1000 MHz

What would you like me to measure?

Walt

Source record: 90319

A very capable engineering colleage of mine mentioned some time ago that an AEA he had purchased worked very well except for one thing -- the reference point appeared to be inside the instrument. He said it was as though there were another length of line (about 5 cm as I recall) inside. For example, measurement of a short circuit would indicate the amount of positive reactance you'd expect from such a line. This might not be too important for general purpose HF use, but would be a problem with some measurements, especially at high frequencies. It could be removed by mathematical adjustment of the measurement results, of course.

I mentioned this problem to the AEA folks at Dayton, not long after it changed hands, and they might have fixed it. Do you see this phenomenon?

I saw a similar thing when I spent a few minutes playing with the very first model of Autek. I don't see this with my MFJ.

Again, the problem might have been fixed, but it's something to look for, particularly on an older used unit.

Dear Walt:
As I remember, and this was a long time ago, the 916's unknown port was less convenient to use than was the case with the 1606. As several have pointed out, one needs a competent detector.
For VHF/UHF work, GR had an "admittance" bridge that worked very well. Used one to tune a 400 MHz feed (of an 85 foot dish) so that the feed was resonant at two frequency bands 60 MHz apart (30 MHz IF strip).
Thanks for the memories.

A correction to what I wrote: I have a CIA-HF from AEA, not a VIA.

Hi Roy,
I briefly owned the AEA V/U model- probably in 1999. Using my HP precision
termination set, it appeared that the best VHF return loss was indicated
when the analyzer was terminated in around 60 Ohms and for UHF it was 75
Ohms. When I called AEA to inquire, I was told "that's about the accuracy
you should expect for $500". The Autek V/U instrument was in excellent
agreement with an HP 8711B.

Not really, it is more like saying there is a word or discussion about 2 wire beverages on page so and so (last few days). Discussion was quite sizable and worth looking into for those who only play with "soft" antennas and see what experiences were gained by those who played with real antennas. It was midnight here and I was closing the shop for the day in anticipation of getting up early. I had no time to go and do the digest or get into arguments of what IS is.
Your data speaks of less than one dB, reality is bit different.
But I know, its me (problem), not the software.
Maybe a little less sarcasm would go longer way?

The charge on a transmission line occupies the entire transmission
line. For instance, there's absolutely nothing prohibiting us from
saying, "Two of the batteries are holding a charge." It doesn't
mean they are holding the same charge or the same charge particles.

Hi all...
I have converted an old cb antenna to an elevated 1/4 wave ground plane cut for 20 meters. I know I can use a 5 watt 100,000 ohm resistor to shut static discharges to ground. How many turns of no 14 enamel wire around a T200 core would it take to do the same job?
thanks in advance, de Denton WB7TDG

Maybe one could coil the wire into a big helical coil where the
current-in is equal to the current-out. :-)

Dear Roy:
Very interesting!
It just did not occur to me to test. Now that the EMC book I have
been helping with is finally being printed (over ten years in the
crafting) I shall put an appraisal of the AEA on our list of activities.
It occurs to me that almost all of my use of the instrument has been
below about 10 MHz. At those frequencies, my suspicions probably were
not tripped by a discrepancy of half a degree (or smaller).
I did buy the instrument after at least one change of hands.
Thank you very much for the heads-up. I am shaking my head in
wonder that that property I never thought to check.
Warm regards, Mac N8TT

> Warm regards, Mac N8TT

A few years ago, I was evaluating an AEA-CIA for a possible magazine review. One of the tests involved a load consisting of some metres of 50 ohm coax terminated in three paralleled 50 ohm chip resistors. When the frequency is swept, this load walks around the SWR=3 circle on a Smith

chart, giving |Z| values ranging between 16 ohms and 150 ohms with a progressively rotating phase; or equivalent results in terms of (R+/-jX). In other words, the test involves only moderately high or low impedances with no nasty surprises.

The AEA-CIA gave good results as a frequency-sweeping SWR meter, and the graphical display is unique in this price range; but unfortunately but it did not give sensible results in the R-X mode (the mode that gives the "Complex Impedance Analyser" its name). In a frequency range where the true value of X was falling progressively through zero, the indicated value came down correctly to about 30 ohms - and then suddenly jumped to 0.0. The R readings continued to change with frequency exactly as expected, but the X reading stayed 'stuck' at precisely 0.0 until the sweep reached the frequency at which X changed sign, whereupon the X readings started to make sense again. This behaviour was totally reproducible. Also, the AEA-CIA is also supposed to be able to resolve the sign of the complex impedance (which it presumably does by changing frequency and noting what happens to X), but perhaps not surprisingly this didn't work reliably either. At a constant frequency where the value of X was nowhere close to zero, the instrument was often unable to make up its mind about the correct sign.

All these symptoms looked like firmware problems to me. Since R and X are both computed from the same analog voltage readings, and R was correct while X was not, the problem had to be in the computation. The AEA management at the time were quick to respond through the UK dealer. They sent me schematics, and analog-type mods to try, and even replaced the entire instrument... which behaved exactly like the one before. However, they didn't seem to understand what I just wrote above, and didn't want to go anywhere near the firmware.

In the end, I abandoned the effort and the UK dealer didn't import the instrument. The magazine decided we should review the MFJ-269 instead - which handled the same test load with good accuracy.

Sorry, I don't recall what specific firmware versions gave these problems with the AEA-CIA, and have no information whether they have been fixed in later versions. As Roy said:

>> the problem might have been fixed, but it's something to look
>> for, particularly on an older used unit.

I've got a 2', more or less, antenna on my truck that works REAL nice on all the bands my scanner will pick up.. I think it's an RT7 or RX7, somethin like that.. Real nice scanner too.. The antenna has a regular antenna thread just like a hamstick or any other popular mobile antenna..

Radio Shack sells a multi band scanner antenna that you might look at. May be able to fashion a copy from it if you're sneaky..

Depends on the core material. T200-WHAT?. Generally, you would want the coil impedance to be at least 10 times the antenna impedance. So, for a 37 Ohm antenna, 370 Ohms. The coil impedance X(L) at 14 MHz is:

X(L) = 6.28 * 14E6 * L

or L = 370/(6.28 * 14E6)

If you ignore the E6, the answer will be in microhenries. So, L=370/(6.28 * 14) = 4.2uH. You will have to look at the chart for your core to see how many turns that takes. For the common T200-2 core, it will be 19 turns, which might not fit. So, use #18 wire - there's very little current flowing through it.

Have you never seen a calculation for the total electrical charge
for the entire planet earth? Charge is a concept, not a particle.

What frequency and what SWR? About 50% of your power would
be lost on 10m with a matched antenna.

Doug:

Kinda depends. <grin>

It depends on the frequency (higher the freq, greater the loss per foot)
It depends on the SWR (higher the SWR, the greater the loss per foot)
It depends on which type of RG-8 you mean.

I suggest using http://www.ocarc.ca/coax.htm (or similar) to calculate the
loss for your run and decide on the cost/loss/ease of installation
trade-offs for yourself.

I know people who use hardline for 80m - they are SERIOUS about putting out
maximum power. They are quite happy with it. I know people who use RG-8X for
6m. They are SERIOUS about keeping costs down and making installation easy.
they are also happy with their choice.

Ceal:

50? that is close to the lose for 8X. For 8/U the loss would be closer to
40% (assuming, as you did, a 1:1 VSWR).

Dear Ian:
Most interesting. Thanks.
I have not used the AEA-CIA for R-X measurements. I always assumed that firmware was used to guess at the sign of X, and it is not too surprising (though disappointing) that the chap who wrote the software might blank out small values of X altogether. [In a spherical navigation program that I wrote long ago for a slow computer, I flagged results that would have been in the noise because of round-off error. It took some effort to know when the results were bad. Others ignored error analysis, being enamored of many random digits, with disastrous results. Sometimes, with computers, no answer is the best one can do. As an example: Cramer's rule just does not work to solve some systems of linear equations using a computer! Even the HP48 uses an iterative technique, which computers are real good at and people are not.]
The most interesting use that I made of the AEA-CIA, which would have been difficult to do with a GR bridge, was measuring the apparent surge impedance of a split boom to be used with a LPDA (prior to the elements being attached). Leaving out the appropriate lecture: I terminated the split-boom with a series of resistors 'till the variation in SWR (seen at the other end of the split-boom) with frequency was minimal. [This is another example of SWR on a line depending on which way one is looking.]

The strong suit of the AEA-CIA is in giving one repeatable data over a wide frequency range. Most of the antennas that I deal with have functional bandwidths of at least an octave. The value of the AEA-CIA is much reduced if one is only interested in what is going on in a narrow bandwidth.

Thanks very much for sharing your experience. We have once again benefited from your experience and Roy's experience. 73 Mac N8TT

I settled for 40 some odd turns of no 14 enamelled wire on the core...as
many turns as I could get on it....swr reads the same as before but the
signal to noise level is a lot better.
this will do until I homebrew a matching network...remotely controlled
variable cap and tapped inductor in parallel at feedpoint...to use the
antenna on 20 thru 10 meters. Unless someone else has a better idea.
In the past, I attached 10 and 15 meter radiators and radials on the same
antenna and it did fairly well on 10 and 15, but I think the gain and
radiation pattern will be a tad better if I go the matching network route.

You're welcome. Just one small point, though:

> I have not used the AEA-CIA for R-X measurements. I always assumed
>that firmware was used to guess at the sign of X, and it is not too
>surprising (though disappointing) that the chap who wrote the software
>might blank out small values of X altogether.

In case anyone's not following this closely, I had been writing about the AEA-CIA blanking out values of X less than about 30 ohms. That is not "small" by any standard, and it only happened on one side of zero. It could not possibly have been a deliberate feature of the programming.

In contrast, the MFJ-269 (and probably the 259B) does deliberately blank out small values - truly small values, that is - as X passes through zero. This occurs exactly as explained in the manual, and is exactly as it should be.

You're right, of course. I looked up the 30 MHz line and the loss is
"about" 1.5 dB per 100 ft. Next time I will use a magnifying glass. :-)

Walter Maxwell, W2DU listed an enviable collection of impedance measuring devices. He`s prepared. Walter also wrote:
"In my impedance-measuring arsenal is the Wayne Kerr B108 admittance bridge. The beautiful aspect of this bridge is that its unknown terminals are balanced, thus allowing direct measurement of balanced lines."

Yes. Balanced unknown terminals are convenient for a commercial shortwave operator located away from the seashore. Horizontal wave polarization with balanced feedlines is economical as compared with coax for high power.

Unbalanced vertical antennas are convenient for groundwaves to extend beyond the horizon for the mediumwave broadcaster. These antennas are conveniently fed by coax of the concentric pipe or skeletal types. All groundwaves are vertically polarized. These can travel very far at low and medium frequencies. Attenuation of high frequency groundwaves is severe. There is no propagation of horizontally polarized groundwaves at all. The low-angle reflected wave is out of phase with the incident wave.

Bottom line is that shortwave broadcasters transmit from horizontal antennas and mediumwave broadcasters transmit from vertical antennas. For shortwave, the target is reached via the ionosphere. For mediumwave, the target is reached via the earth`s surface which is involved in reaching beyond the line of sight.

For a dipole, you are likely to prefer a balanced bridge. For a monopole, you are likely to prefer an unbalanced bridge.

Best regards, Richard Harrison, KB5WZI

I have the same rig. (the later HTX-10 has a better receiver, but lacks CW) I believe the mike UNIT is limited to Radio Shack, but using the schematic you should be able to set up a remote control system like I did- boom mike clipped to headphones, footswich for tx/rx switching and pushbuttons for up/down use.

Good luck, and enjoy it- it's not a bad rig for the price! (and just wait for the sunspot count to rise again...hubba hubba!!)

Of course you could, but I wouldn't run it that long.
the higher the frequency, the more loss you'll have - so if you operate on 80meters the loss won't hurt 'as bad' as if you operated on 10meters or 2 meters.
move your shack up closer to the antenna - or use ladder line

Richard -

First, do the obvious and contact Radio Shack.
They have a web site, an 800 number and technical support.

What you want to know is if the replacement microphone is still available,
its part number and cost.
Much of this is now "on-line at Radio Shack
http://support.radioshack.com/productinfo/DocumentResults.asp?sku_id=19-1101&Name=Ham%20and%20Marine%20Radios&Reuse=N

190-1101 MOBIL TRANSCEIVER HTX-100 Faxback Doc. # 21286
To order parts call 1-800-843-7422 or visit your local RadioShack store.

MC501 10804706 MICROPHONE,COMPLETE MK389 MA0020
10804706 600 OHM,DYNAMIC MA0020

So there is your part number and phone number ... probably be less painful
and cheaper than adapting a microphone you would buy.

With a groundwaves there is no reflected wave and incident wave to get out of phase with each other. By definition, it is all in the ground down to one skin depth.

Very simply, a horizontally polarised groundwave, with its horizontal current, suffers great attenuation in the loss resistance of the horizontal ground. It gets launched but after one or two wavelengths it is many decibels down.

This is the reason why horizontally polarised noise, relatively locally generated, is smaller than the vertically polarised variety although, on the average, both are randomly generated with equal amplitudes.

Half of the total noise power is dissipated in the ground except that which is generated immediately adjacent to your receiving antenna.

Reg, G4FGQ

2535. Copper antennas:

I just got back from Home Depot and the sell some treated (nasty
smelling) 2 x 2 deck post that are 3 feet long for $.99 each. I will be
using one at the top and one at the bottom to keep the antenna wire away
from the tower. I stripped the old stuff off the tower this week and
hope to have the 160 meter Inverted-L for RTTY up in a week or so. I am
getting too old for this tower climbing stuff. HiHi

Thanks for the excellent suggestions.

There probably isn't even a perceptible difference in reception between aluminum, copper or stainless. Copper is easy to work with at VHF and above because you are dealing with fairly short sections. A copper yagi for 20 Meters, for example, would be quite unwieldy. The nicest thing about copper is that it is easy to make feedline connections to it...solder works fine. With the other metals, you need to rely more on mechanical connections such as ring lugs, bolts and nuts, etc. What band of frequencies are you planning to build for?

The ARRL Antenna Book is a good place to start learning about antennas. You should be able to find it at http://www.arrl.org and order online there as well.

Another site is http://ac6v.com/swl.htm#ANT if you are looking for SWL antennas.

Mickey,

Stainless steel is not as good a conductor as copper. It is used for mechanical reasons primarily.

Yuri Blanarovich wrote:
> "Becomes very lossy" or paraphrased "lose its conductivity" to make the point?

I agree that a wire laid on the ground does not become very lossy
although energy is lost to the lossy medium in proximity to the wire.
What is happening is decreasing ExH power caused by field attenuation
in the ground. In free space, the E-field causes an equal energy H-field
which causes an equal energy E-field, ad infinitum. In the presence of a
lossy medium, like earth, the fields undergo an attenuation factor so
that each field strength is less than the previous cycle. The decrease
of the voltage and the current on/in the wire on the ground is *caused*
by the attenuation of the surrounding fields and would occur even if
the wire were a super-conductor. The wire itself does not "become very
lossy". The ground around the wire becomes very lossy.

Consider the power transferred through a transformer. The primary
has highly conductive insulated wire but "loses" virtually all of
its power, not through conduction, but through induction, to the
secondary. The losses through an insulated wire laid on the ground
are through induction, not conduction.

Copper is the best except for silver. The problems with either is the cost
and mechanical strength. Wind will usually bend copper tubing and it will
not spring back like the antenna grade aluminum.
There is a very slight (probably not even enough to notice) differance for
the beter with copper over SS or aluminum.
If you can keep the wind dammagd down , then go with the copper tubing.

Weight considerations aside, if you are building a copper antenna with
soldered fittings, use silver solder. The normal resin-core solder will
not stand up to vibration from wind and other things.

Hi Mickey

Copper is GREAT for Antenna's!
It's only slightly heavier than Aluminum.
But their are MAJOR advantages to using copper.
Solid corrosion free joints is only one of them.

There are three (without getting technical) basic copper tubing types
available. Soft Copper (easily bendable), Hard Copper (water pipes,
which can be swedged under heat), and Annealed Copper (refrigeration
tubing).
Regular Hard Copper water tubing is sufficient for most antenna work.
But if your building something like a long Yagi, you definately will
want to use Anneled Copper for the boom or you will wake up with
U-shaped Yagi one morning.
You can also often work in smaller pipe sizes when using the Annealed
Copper as well. Such as 1/2 inch Annealed instead of 3/4 inch Hard.
Even the soft copper comes in handy for some non-supporting components
such as coils and the like.

When joining copper using fittings or swedged joints use either
standard plumbing methods or preferrably silver solder in these
joints. When building things like Yagi's where you may be passing the
elements through the boom without using fittings, copper phosphorus
bronze brazing rods work at propane torch temperatures and make a more
secure joint than silver solder on these types of connections.

Where electrical connections need to be made (and often may need
changing or maintenance) I found that adding a soft copper tube or
heavy copper wire, affixing it to the antenna with copper phosphorus
bronze, allows a good soldering gun and rosin core solder to make the
electrical connection to the pigtail installed for this purpose.

I certainly hope you can personally select the posts you buy.
You, of course, don't wany any with knots in them!
And, _that_ may be why they are $.99 each. HI!HI!

In a similar thread, I suggested the use of fiberglass replacement
tool handles. Something like a grass rake handle should Fit The Bill.

That's what I use for a stand-off (stand-away?) for the mid-point of my
75M/40M Inverted Vee's. I painted it "Rohn Grey" before installing it.

I was Very Lucky: When I went to the local ACE H/W Store, they _gave_
me a cut-off for free. Seems they got a shipment of Very Defective
shovels, and headquarters told them not to send them back -- but,
rather, to cut the handles off the shovels (which were the defective
component -- they split [!!] down the center under heavy, but reasonable
use) and to toss'em in the dumpster. Well, the folks at the ACE here
are about as commited a set of scroungers as I am. They threw out
the shovels and stored the handles in a large barrel in the back lot.

Reg, you are correct, of course, but Richard H. said above, "There is no propagation of horizontally polarized groundwaves at all. The low-angle reflected wave is out of phase with the incident wave."

What Richard mean't concerning the 'reflected' wave is that the energy radiated downward from a horizontal antenna is reflected by the ground, and that reflected wave is out of phase with the incident wave.

Richard, when I was doing AM BC consulting more than 50 years ago I made the observation from FCC ground-wave distance vs frequency propagation charts that with the same ground conductivity and 1/4 wl antennas for both frequencies, the 1mv/m contour attained by 100 w at 540 kHz would require slightly less than 50 Kw at 1500 kHz,

Proves your point, doesn't it?

When I worked for the Schlumberger Oil Well Surveying Corp., I
used to run an "induction log" on freshly drilled wells before
the casing was set while the hole was filled with "mud". In basic
terms, it worked like a transformer. The primary would create an
inductive field in a donut shape out in the formation. That inductive
field would generate a voltage in the secondary of the transformer.
A little processing of the received signal yielded the conductivity
of the formation, high for shale and salt water, low for fresh water
and oil, lower for gas - same principle as metal detectors.

We also had a cheaper "electrical log" which was simply two conductive
electrodes at each end of a wire-line sonde between which conduction
current was measured. Not nearly as accurate as the induction log
because it was highly affected by the fresh water used to make the mud.

Source record: 90172

Although a reflected horizontally polarized wave is out of phase with
the incident wave, and this explains the zero far field strength you get
with horizontally polarized waves, I'm not sure this is the relevant
explanation for the lack of ground wave propagation. The reason I doubt
it is that if you do the same analysis for vertically polarized waves,
you find that the net field strength is also zero at zero elevation
angle, except for the special case where ground is perfectly conducting.
So using the same analysis, you'd have to conclude that vertically
polarized waves can't propagate by ground wave, either.

Roy Lewallen, W7EL

I`ll turn to the authors for a source of my contention.

Terman says in his 1955 edition on page 803:
"The ground wave is vertically polarized, because any horizontal component of electric field in contact with the earth is short-circuited by the earth."

And on page 808, Terman says:
"Examination of these vector diagrams shows that with a perfect reflector the horizontal components of electric field will exactly cancel each other at the surface of the perfect conductor. In contrast, the vertical components of the electric field of the incident and reflected waves do not cancel, but rather add at the reflector surface with small values of earth reflection angle."

Best regards, Richard Harrison, KB5WZI

Roy, W7EL wrote:
"So using the same analysis, you`d have to conclude that vertically polarized waves can`t propagate by ground waves either."

Earth isn`t perfectly conductive but even so permits propagation of vertically polarized waves.

Another expert, Kraus says on page 412 of his 1950 edition of "Antennas":
"The electric field of a wave traveling along a perfectly conducting surface is perpendicular to the surface....However, if the surface is an imperfect conductor, such as the earth`s surface or ground, the electric-field lines have a forward tilt near the surface.... Hence, the field at the surface has a vertical component Ey and a horizontal component Ex. The component Ex is associated with that part of the wave that enters the surface and is dissipated in heat. The Ey component continues to travel along the surface.

i have yet to see one at a US broadcast station. the meter that is usually
found, and used is the delta OIB-1 or OIB-3
http://www.deltaelectronics.com/data/oib1&3.htm

It's very nearly the same as it's predecessor, the GR 916-A,

Walter Maxwell, W2DU wrote:
"The Beverage was more than one-half mile long at a height of 10 feet, aimed directly at Tokyo, and terminated with a variable resistor."

2 wavelengths at 650 KHz is a little more than 1/2 mile and is likely the point of diminishing returns in lengthening a Beverage according to some reports.

I used a Beverage in Portugal to listen to the CBS Nightly News from WCBS in New York or from WWL in New Orleans, whichever was better at the time. Both carried the same program and were adjacent points on the frequency dial. It worked like a charm using a SP-600.

RFE constantly monitored news and commentary broadcasts from behind the "iron curtain" during the "cold war" from a receiving station in Germany. A multitower directional array and various super loopsticks were used to pick out the broadcasts monitored. These were more flexible than Beverages and many possible sources were available for programs to be monitored.

>It's only slightly heavier than Aluminum.
>But their are MAJOR advantages to using copper.
>Solid corrosion free joints is only one of them.

Due to the skin effect, RF currents only flow on the surface of the conductor. At VHF frequencies, the skin depth in copper is only about 5 um, in which nearly all RF currents flow, thus the low resistivity of this thin surface layer is critical. From RF point of view, it does not matter much what is below this surface, so it might be empty (a tube) or it might be something with lower conductivity, such as stainless steel (with much greater mechanical strength).

However, if the antenna is not protected by a radome, the weather will within a few years affect the copper surface, creating oxides and the copper becomes green or dark brown. Now the question is, what is the conductivity of these surface layers. If these layers are isolators, the RF current will flow in the clean copper below, but if the layers have some mediocre conductivity, part of the RF current will flow in these oxide layers, increasing the total resistance.

This should not be areal problem with VHF antennas made of tubes, since the length to surface ratio is quite small.

Mike Beauchamp wrote:
"Can anyone tell me what the proper formula for finding a odd multiple in inches would be?"

Wavelength in meters is 300 divided by frequency in MHz. A meter is 39.37 inches. Reduce the antenna length by about 5% for "end effect". A balanced antenna is often 1/2-wavelength. An unbalanced antenna is often 1/4-wavelength. Antennas are usually nnear self-resonant lengths to avoid reactive opposition to antenna current.

Search on VHF antenna lengths. For an odd frequency multiple, divide the fundamental frequency length by the order of the multiple. For 3X the frequency, the length will be approximately 1/3 the fundamental length.

Always cut the calculated lengths a little long. It`s easier to trim to length than to augment a too short antenna in most cases.

I think the mike connection pin out for your HTX-100 and the Kenwood
HF transceivers are the same. Look in your owner's manual and then
the mike connector at Kenwood's web sight. See if they are the same.
If so, and you cant find a RS replacement, get a Kenwood microphone.

Another plus of this is used in some high-powered industrial equipment
that uses RF, and I believe some broadcast equipment. For cooling,
copper tubing is used as the RF conductor (skin effect only) and water
is pumped through the inside. A few tricks of the trade, like using
pure water without dissolved ions, and connecting the plumbing with
non-metal parts to isolate the RF, are involved.

Sometimes the copper is plated with silver, not so much for better
conductivity as the better oxidation properties of exposed silver.
Gold would be a bit better, even if a lot tougher on the budget.

2567. The exciting world of APRS

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-30 12:13:38 UTC
From: hxc98@yahoo.com
Message-ID: <aa8577c5.0408300413.52f3cdf@posting.google.com>
Source record: 90188

Start learning about the exciting world of APRS with APRSPoint, the APRS software regarded by most hams as having the best map support and most intuitive user interface. Track other hams on a zoomable, street-level detail map in an intuitive and easy to use interface. Send instant short messages through either RF or internet link. If you are an experienced APRS user, you'll appreciate the ability to plot a digipeater or other ham stations' signal range on the map, connect to APRS internet servers, send email through your ham radio, and other advanced features. This week you can get APRSPoint with MapPoint 2004 included for the best possible price ever. Check out the website at http://www.aprspoint.com/ for details.

That`s exactly the structure of the final amplifier tank coil of the 100KW GE watercooled shortwave transmitters used at RFE. The coil was silver plated. We distilled our own cooling water and the water circulation system was connected by Saran tubing. Though many KV were applied to the plates, d-c leakage was insignificant.

Almost like I have seen high powered RF coils like this. ;-)

I've seen them, used them, and fixed them. I think the biggest system I worked on was a mere 25 or 30 kV. Not broadcast, but plasma generating process equipment.

Only so many reasoanble ways to solve this problem.

Your water cooling does need to be able to handle the heat generated by significant mismatches, not just ideal operation. It is bad luck to melt parts of your cooling system.

It`s worth a try but may not result in a clear picture. I`ve fought that battle from the roof of the almost highest building in town. You are probably at about 650 feet and the TV horizon if visible would be about 36 miles away. Line of sight may have little to do with your problem. Other structures in a city reflect delayed signals in your direction, blurring your reception.

You need high directivity to "turn a blind eye" to the multiple reflections.

Hi Tim,

I can't disagree with you here, because my knowledge is from several years back.
I'm not familiar the Delta except by reputation--all I've heard is that it's a
good instrument. The demise of General Radio is probably one reason the GR
instrument is no longer the instrument of choice, so the dividing line between
use of the GR and the Delta probably defines the end of one era and the
beginning of another.

Roy, W7EL wrote:
"Notice that I said that the wire was most likely to be a problem with antennas on the order of an 80 meter dipole length."

80 meters isn`t the lowest nor the highest frequency ham band, but could be a problem for various reasons. Loss is directly proportional to resistance in the familiar current squared times resistance formula.

Resistance increases due to skin effect only as the square root of the frequency while resistance varies directly with the conductor length which varies inversely with frequency.

Loss gets worse for a given wire size as frequency drops because you need longer wire for a 1/4 wavelength. It doesn`t get worse as fast as it would if there were no skin effect because as frequency lowers, current penetration grows and wire resistance drops due to reduction of the skin effect. But, the longer wire is inevitable along with its higher resistance at the lower frequency.

At RFE, as soon as a new frequency became available we would often erect a Signal Corps rhombic kit and start broadcasting. These weren`t made for 100KW so the dissipation lines soon melted and the rhombics became bidirectional.

At the end of WW-2, many Central Europeans fled to South America. When we strengthened and replaced our dissipation lines, we discovered we had built a large loyal audience among the fugitives. Not too surprising since we were programming with some of their favorite entertainers who were also exiles. Too bad we had to eliminate the signal flooding South America, but other broadcasters had claims on the frequencies we were using for a South American audience.

Indeed. I used to do MATV systems in Honolulu.
There, the TV transmitters are right in the middle of town.
One is about a block from a 25 story building, and of course a bunch of
others, and you're trying to get a good signal in the concrete jungle of
Waikiki..

We used "deep fringe" yagis, and large attenuators (20-30dB) then amplifiers
to drive the feeders.

Very interesting, Richard. Were the rhombic dissipation lines made of high resistance wire? And where were the transmitters located that flooded SA? And what SA countries did the fugitives concentrate in?

Hi group!

I've search on the Internett to find som instruktion on building a W3DZZ antenna.
Have someone some drawings on it?
Or have someone of you drawings on other easy made multiband antenna?

> stainless steel (with much greater mechanical strength). . .

You're correct that most of the current flows in the first skin depth, but a signficant fraction, 37%, does flow at greater depths. (This number is both the fraction of the surface current density at one skin depth and the fraction of the total current that's below that depth.) The current density at 3 skin depths is 1/e^3 or about 5% of the density at the surface, and at 5 skin depths, 1/e^5 = 0.7% of the density at the surface. So it's reasonable to state that the material below a depth of a *few* skin depths isn't important. At RF with metallic conductors, a tube with any reasonable wall thickness is at least several skin depths thick, so I have no disagreement at all with the conclusion.

Regarding the importance of the material resistivity, it can be argued that it's actually less important at RF than at DC. The reason is that the skin depth is greater when the resistivity is greater. If a material is twice as resistive as, say, copper, the skin depth will be sqrt(2) times as great, resulting in an RF resistance which is sqrt(2) -- about 1.4 times -- greater than copper rather than twice as great.

I hope none of this has detracted the original poster's attention from the good advice given early on in the thread -- that virtually any metal is just fine for his receiving antenna. He won't be able to notice the difference between one and the other. There are two reasons for this:

1. The efficiency of most common antennas is so high that making them out of even quite poor conductors won't reduce the efficiency enough to be able to notice or even measure; and more importantly,

2. Efficiency doesn't matter anyway for HF receiving antennas, except in very special cases where the antenna is extremely inefficient and the receiver noise figure is extraordinarily high.

There are situations where it's important to pay attention to material conductivity and to understand skin effect. This isn't one of them.

2580. Re: Stainless Steel Wire - OK for antennas?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-08-30 18:57:50 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cgvtbeklq1@titan.btinternet.com>
Source record: 90201

There's been much discussion.

The end-to-end RF loss resistance of a half-wave copper dipole is given by -

R = Squareroot(Lambda / 2) / D ohms.

Where Lambda is the free-space wavelength in meters and D is wire or rod diameter in millimetres. Much more simple and easier than measuring it.

For example, the overall loss resistance of a 14 awg, 40m dipole, is 2.73 ohms.

For another metal, multiply R by the square root of resistivity and the square root of permeability, both relative to copper.

Reg, GFGQ

2581. Re: Copper antennas:

Newsgroup: rec.radio.amateur.antenna

From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cgvugb$888$1@hercules.btinternet.com>
Source record: 90202

The RF resistance of a wire is the same as the DC resistance of a tube of
the same outer diameter and a wall thickness equal to skin depth.

This allows a pictorial representation of what takes place.

Ian, and others,

I have the 269 HF VHF UHF analyzer and noticed something strange. In the "non-50 ohm" Advanced menu 3 mode, with the Zo set to 75 ohms, an otherwise good 75 ohm load (please assume I know how to tell and I used a low frequency to reduce errors) shows something like a 1.3 : 1 SWR. When I called to ask about it, the first tech at MFJ seemed confused and clearly did not understand. Another call, on another day resulted in a better tech, but the response was to send it in for re-calibration. This also seems to be a calculation rather than an adjustment, no?

Once you know Z it is a simple calculation to get to SWR for another Zo. Or have I been smoking a bad brand...?

Woha! I see they have on line calibration manual for the 259B & 269 on line!
http://www.mfjenterprises.com/MFJ-259Bcalibration.php
http://www.mfjenterprises.com/man/pdf/MFJ-269_Calibration.pdf

I don't see anything other than "watch the blinking SWR" .(sounds like a British insult) for the Advance 3 "calibration".

You have to use more wire, and more wire is better. At the 64' height, a simple fan dipole or inverted vee for 40 and 80 ought to produce the same results. Efficiency, bandwidth, impedance, and pattern will all be about the same. I wonder what you do if you can't get the center up 64'?

Walter, W2DU wrote:
"Were the rhombic dissipation lines made of high resistance wire?"

The Signal Corps rhombic kits we had were manufactured by the Wind Turbine Company and were most distinguished by a unique one-piece ceramic insulator designed to hold both transmission line cables as it sat atop a support. The lines were made of 3 no. 12 Copperweld wires twisted together. We discarded these as our transmission lines needed larger cable and wider spacing for the same 600-ohm line.

The kit included short tower sections meant as transmission line supports. Triangular tower sections were made of (3) vertical steel rods with wire sides where the wire weaved back and forth between rods. Every steel piece was welded at intersections and assemblies were all hot-dipped galvanized. They were good structures.

The rhombic curtain was a 3-cable type, spread apart vertically at the side towers to reduce impedance variations. The same Copperweld cable, (3) twisted no. 12`s, was used for each of the 3 separate cables, as that used in the transmission line.

An exponentially tapered feedline was used to attach the wide-spaced attachment to the curtain overhead to the more narrow transmission line down below. Its aim was matching 800 ohms to 600 ohms.

My recollection is that the dissipation line at the far end of the rhombic terminus was itself made to match 800 ohms rather than using another tapered line. Too many insulators of varied size, I suppose. So, the down line at the far end had uniform spacing. The dissipation line itself was relatively small stainless steel wires until we replaced them with much larger wire and spacings. It ran back and forth down the centerline of the rhombic.

The rhombics were aimed at central Europe from Portugal. Their reverse radiation bathed nearly all of South America with strong signals for as long as the rhombics were without dissipation lines.

I have no statistics on where the fugitives concentrated. I know that before WW-2, many Europeans had sought opportunity in South America. The war made it plain that the persecuted needed a new haven outside of Europe. It was also clear that the persecutors might escape responsibility if they fled Europe following the war.

I`ve personally been struck by the numbers of people I`ve encountered in Santiago de Chile, Buenos Aires, and Rio de Janeiro, obviously residents, not tourists, speaking Central European languages. A lot of these newer arrivals already had families residing in those countries.

There are a lot of Brits in South America too. In Argentina, many came to do good and stayed to do well. Hurlingjham is a British neighborhood in B.A. with its own polo grounds. People send their fourth generation offspring back "home to the U.K." for education. The main street (high road) of Santiago is Avenida O`Higgins.

Get real, Tom. Does your vehicle battery hold a charge? Is that charge
an infinitesimal point charge? Introducing an infinitesimal charge into
the argument at this late point is known in logic as diverting the issue.

The charge on your battery is a total charge. The charge in a transmission
line is a total charge. The charge of the planet earth is a total charge.
Charge is moving in opposite directions 1/2WL apart in a transmission line.
Charge is NOT limited to an infinitesimal charged particle, as you imply.
Charge is a characteristic of *any* number of particles in *any* magnitude
of volume including, presumably, the entire universe.

The problem is the same as for an HT -- your body is just as much a part of the antenna as the "antenna". If you can figure out how to make a good model of your body, you can model it. I'm sure someone, somwhere, has done some work on this but I don't know how good the results might have been.

"Charge is NOT limited to an infinitesimal charged particle, as you imply."

True, but charge has a force characteristic. The electron has a charge of -1, or, the value of negative charge carried by an electron is one. A coulomb is (6.281 times 10 to the 18th power) times the charge carried by one electron. A coulomb per second past a particular point is also one ampere.

I have long thought that electrical charges, individually, likely have random motions but that an ampere is the net result of more charges moving one way than another.

With so many small charges involved in a net substantial charge flow, why shouldn`t charges be moving in two or more directions at once?

Best regards, Richard Harrison, KB5WZI

in part, the OIB (Operating Impedance Bridge) is popular because the normal
transmitter is the (usual) frequency source and interruptions to

transmissions can be brief or non-existent.
in typical use the bridge is inserted using a hot jack or J plug.
the engineer must be careful at all time to avoid touching exposed RF as the resulting burns are painful and long lasting.
the meter itself has some effect on the circuit tuning: sometimes a permanent version is installed at the common point of a phased array.
sometimes special jacks are employed that add a bit of inductance when the meter is removed.

I didn't check this feature as part of the review, but it should be simply the inverse ratio of whatever resistances you choose to define as your Zo values.

The MFJ-269 had to go back after the review (which itself was a few years ago) so unfortunately I'm no longer able to check your findings, Steve.

But don't recalibrate it yet, because that would be stirring-in additional variables which will muddy the waters right now. After the present question has been resolved, you may be able to give the calibration procedure a little more TLC than there was time for on the production-line - but you'll need some precision standards to do it.

Do I need a dogbone or egg insulator at each end of my dipole, or can I just splice the antenna wire to the nylon braid that runs to my trees?

Is the answer different for, say, under 100 watts vs 1,000 watts? HF vs. VHF?

I would probably put a small nylon thimble in the nylon braid to provide a decent radius for the wire end.

Answer: maybe. The nylon braid is OK so long as it never gets wet and
absorbs water or if you let it thoroughly dry before transmitting.

I bought my XYL a high-$$$ all-band vertical and a tuner. It rained hard
one night. The next AM she noted that she had to retune to get the SWR
normal but she fired up her 100 watts and made several QSO's. Then she
barely heard an old friend signing off with another station so she turned on
her 'killer-watt' and called him. They'd barely got thru exchanging calls
and into the pleasantries when she noticed a smell ..... luckily only the
tubes were fried. She turned off the amp and saw that the SWR was out of
sight - until she returned the tuner to it's usual settings for that freq.
I was soon swinging from the trees installing dipoles for each band -- with
insulators!

Hi Vito, I don't see any connection between frying tubes on an amp from an "all band vertical" with tuner settings that were not "it's usual settings for that freq", and having no egg-type insulators on the ends of a dipole - did I miss something here?

I never installed the eggs on the lower antennas (fan type) of my dipole (ran out of them at the time), and when it offered SWR of 1:1 performance dry or in pouring rain, I just left the original copper wire to nylon line tie-off alone. Been up for a year with no problems ever.

Thanks, Tim, for the update on the OIB. It did refresh my memory concerning the
meter being used while the transmitter is on the air. That I now recall.

The simplest answer is that charges move in response to the local
electric field they experience. That field has only one value at that
point, at that instant, and is determined by the superposition of all
local electric fields.

Yep! An extensive sheck of known good loads showed that the MFJ was
working as expected with reasonable accuracy. I don't have numbers, but 50
ohm loads looked ok and SWR, Z etc all appeared to be reasonable. Just this
one problem. (I have access to Agilent "N" cal kits)

The problem is the I found nothing wrong when measuring in all the other modes. Only this one problem and I believe this is a calculation in the microprocessor, not anything that can be "calibrated" to correct. I was asking if this is correct. I also see nothing in the MFJ cal procedure for the 269 for this mode other than "watch the blinkin' SWR symbol" (I indicates you have set a Zo other than 50.

Thanks Roy. Mine shows it to measure 75 normally, but 1.3:1 in the Advanced
3 @75 ohms. Either I better change my brand of smokes or the Micro forgot
how to do the calculation... Better go back and try again to see it I
goofed somewhere...but I've done that several times..... . . . . .
. .

Am I correct about this being simply a calculation?

Hi All,

Buenos Aires certainly does not lack for Spanish names in its various barrios and along its streets, but not all of them are mono-cultural. Notable in both their in-country airport and a road nearby is the name Jorge Newberry. The Thames can be found in Palermo. You can stay the night in the Hotel Waldorf or Hotel Lancaster in the Retiro and shop at Kelly's - the Irish Embassy is also located in this barrio. There is also the British Arts Center in the Retiro, as well as the Torre de los Ingleses (a monument to the English) across the street from the Plaza Libertador General San Martin (which contains a wall of names of the fallen in the Malvinas).

When I visited the Cementario de la Recoleta there were plenty of English and Irish surnames from 150 years ago - not unusual at all. However, Buenos Aires also sports a very large population of Italians and is the home to the largest settlement of Jews outside of Europe and the US. When we were in La Plata, we ate at schnitzel at a Bavarian styled restaurant.

>point, at that instant, and is determined by the superposition of all
>local electric fields.

If you presume the simplest answer, it still entails complexity in
that this is more correctly called "directed drift" wherein the motion
of the chargeS are random within a locality, but in the aggregate and
as an average tend in one direction.

This sort of dovetails with recent postings by Art speculating about
charge accelerating (without needing power mind you) in the circle of
a loop antenna. The truth of the matter is that those electrons/holes
would never move in a circle, nor even an arc given the short distance
of the net migration being very much less than the diameter of a
small, small wire (and at any HF frequency, infinitesimal).

Hi Jim, we missed you.

For RF, it is certainly possible for the network charges, at t(x), to
be moving in the opposite direction from force exerted by the network
electric field (voltage) at t(x). Remember, dQ/dt can have a different
sign from the sign of the electric field voltage. This ain't DC.

I'm sure it's a calculation. I believe it was you who pointed out that once you know the Z, you can calculate the SWR for any Z0. And you don't need to know the sign of the reactance in order to do it. So that's surely the way it's done.

Can't imagine that yours does the calculation different than mine. . . hm, maybe it does. . .mine says "Ver. 1.24" when it starts up. What does yours say?

Hi Sarah, you don't need Morse code to become a ham. A good percentage
of hams don't know Morse code. How about you get your Tech license first?
The Tech license doesn't require code. Then you can decide what to do next.

You don't need morse code to get a ham licence anymore, but if you want to learn code, I could reccomend SuperMorse or NuMorse This is what worked for me.

Good luck, and I hope to run into you on the air one day.

A guy I spoke with a while ago, runs a number of point-to-point networks of 7-10 miles, using standard (nonamplified) 802.11b cards (typically around 30 milliwatts) and parabolic/Yagi gain antennas in the 18-21 dBi range. He said that this combination leaves him with plenty of fade margin... he was not complementary about people who create such links by just "blasting away" with high-power transmitters and low-gain antennas.

On a miles-per-dollar basis, I think you'd get the best results by using high-gain antennas, with the cards / access points mounted right at the antenna. Run an Ethernet cable up the mast, and use the extra two pairs in the cable to carry DC. This will minimize signal loss in the coax, which adds up very fast at 2.4 GHz, and may save you the high cost of low-loss 2.4-gig coax or hardline and the even higher cost of a good amplifier.

Amplifiers are rather expensive, and there are some significant regulatory issues involved in their use. It's not difficult to push your ERP up above the level that Part 15 allows... when you do, you have to start playing by Part 97 rules (assuming that you have a ham license) with all of the frequency and usage restrictions that come with this Part. Some vendors will not sell higher-powered 2.4-gig amplifiers except to people who can prove that they have ham licenses.

http://www.wlanparts.com/ is one source for such antennas.

http://www.maxrad.com/ is another, although their products seem to be commercial-premium-quality and are priced accordingly.

Uh, OK if you get away with it. But you do know that the highest currents
are at the ends of a dipole, right? Hence, you *could* set something afire!
No joy.

I like morse code. My dad not done it in 10 yars. He is learning it agin. He
is learning really fast. I do not like his program. I want to build my on
radio.I saw a one tube radio I think I can build if dadd helps. What is a
807? I built a trnsistor blinker in 4H.Daddy calls it a multivibater. I put
all the parts on the board and solered it by myself. It worked the first
time.I learned to solder helping mom and dad make stianed glass stuff.
solder is fun.My friend Jenifer is learning code to. Her dad hams too. Jenny
says that is all he ever does.Mom says time to go to bed.

Actually, the current is lowest and the voltage highest at the ends of a dipole.

Someone wrote:
"----the EMF on the antenna will cause it to vibrate in the earth`s magnetic field, and while this motion is extremely small, considering the relative wavelength and propagation speeds, an exact analysis may find that it is similar to the speaker`s cone motion when reproducing music."

Inertia causes things at rest to tend to remain at rest and not to respond to casual stimulation. Only the resonant reed responds in the vibrating reed frequency meter. Likewise, one can, with enough excitation, get a d-c meter to try to track the a-c voltage cycle of a very low-frequency oscillator. But, as one increases the frequency a point is soon reached where the d-c meter needle falls to zero and won`t budge in response to the a-c excitation. The needle assembly just has too much inertia to be moved before its excitation impulse is reversed. All the needle can do is stay put.

In the case of an antenna stimulated at a radio frequency, I think physical response is out of the question due to inertia. Further, I`ve observed countless towers and wire antennas audibly singing in the wind, but never noted any Doppler effect on the radio signal.

Best regards, Richard Harrison, KB5WZI

Sarah
Your Pa is right, it's best to learn code if you want to become a good Ham Operator. It really isn't that hard to learn. It's a lot of fun and you never know when it will be needed for emergencies or contests. Go ahead and get your Tech if you want first and then go for an upgrade. You'll need to know code then.
Good luck.

Well not really, the highest "Voltages" are at the ends of a dipole, and
if one were to exceed the breakdown voltage of the insulating support
line then one could expect the possibility of problem. Other than that
it doesn't really make a difference.

Very very very small especially when the Doppler effect is relative to
the speed of light and not sound. Also it would have to vibrate at RF
frequencies.

> >

> > circumstances.

But if you consider both the 50 Hz and 4 kHz vibrations cone, the
sound source at 4 kHz (wherever you consider it be) is certainly
moving at 50 Hz. Even if you consider the center of motion at 4 kHz
to be the sound source, that center is moving at 50 Hz. That is the
entire point!

And thus another radio-myth is dispelled....

I doubt anyone disagrees that insulators which help support the radio apparatus industry, er, I mean the ends of the dipole, are "proper" connections. But I'll gladly show pictures to anyone who doubts that the (8.9 mhz length) 1/4 wave ends of my dipole are operating that way. And there is indisputable evidence I have operated this way at very long ranges during icestorms, torrential downpours, and even hurricanes. Never saw a noticeable variation in the consistent 1.1 to 1 SWR as indicated on the tuner. So the 30 odd feet of string holding the ends of the 8mhz components of the dipole are definitely not robbing it or shorting out.

I also doubt Marconi would have a problem with that!

Jack

I guess it just depends on how often you want to re-hang an antenna.
The antenna wire will certainly cut through the nylon string or cord
far quicker than it will a ceramic or polymer-type dogbone or egg.

Hi Bob, if there was any tension on the connection that is certainly correct. I noted that my 8mhz component was so attached - but it only hangs below the main element, which does use the egg-insulators. There is no strain on the lower components at all, so the only factor involved is that there is no noticeable affect from rain, ice etc on a non-insulated connection there. If those elements disconnected at the ends, I could reach them from a tall step ladder. Any high connections that would require antenna lowering to repair should certainly be made with permanence in mind!

I have an IC-229H 2M radio that I am using with a HM 56a microphone. The radio keys as soon as I turn it on with the microphone connected. First is this the right mike to use with this radio. Been a few years since I last used it. The connector has been resoldered but I think I did this to fix a broken wire. Wiring diagram with wire colors, pin numbers would be most helpful.Really think it is the right mike and dont really think it is wired wrong but both are possibilities, Any other help would also be appreciated.

2651. unOfficial NEC Archives update

Newsgroup: rec.radio.amateur.antenna
Date: 2004-09-01 18:38:03 UTC
From: Ray Anderson <reanderson@sbcglobal.net>
Message-ID: <fGoZc.10564$QJ3.2529@newssvr21.news.prodigy.com>
Source record: 90074

NEC Archive users:

Lately the server holding the unOfficial NEC Archives (http:///www.qsl.net/wb6tpu) has become so slow as to almost be unusable for downloads due to overloading on the system. (There are presently 50,000+ (yes, 50K) web pages being hosted on the Dual 1.2 GHz Pentium III Linux box that hosts the archives.)

In the interests of keeping the archives a viable and accessible resource I have moved the content of the archives to the server that hosts the www.si-list.org web pages (si-list is a Signal Integrity oriented discussion list). The archives can be accessed at the following address: http://www.si-list.org/swindex2.html

Since the http://www.qsl.net/wb6tpu address is a well known portal (Google shows 29,000+ references on the web) the page pointers on that site have been adjusted to point to the new location at si-list.org.

Downloads that have been taking 'forever' or timing out with a transfer rate of about 0.3kB/s on the qsl.net site now clip along at about 100kB/s on the si-list.org site.

I'll probably be fine-tuning things a bit and removing any bugs that crept in as the result of the transfer, but the new location is accessible and fully functional at this time.

Sarah> me learn.

I have some software which generates new MP3s every night using the
Koch method (described elsewhere in this thread) and Farnsworth
spacing. The spacing allows you to concentrate on the characters at
full speed without hearing them rushed together too fast, and the
method allows you to learn one character at a time. All you have to
do is click on the MP3s and they should play just like any music you
play at home. Write down the letters as you hear them, and compare
your results to the text file also on the page, and soon you'll be
able to use CW on the air!

Jimmie,
If any of the touch tone buttons are sticking it will key the
transmitter when you turn it on. I am assuming that the HM56 and HM56A
are the same.
If you need a manual for your 229 H, send me your mailing address and I
will send you a copy free of charge. The file is too large to email.

Thank you Ray. You are providing an invaluable resource.

I personally am finding 4NEC2 a powerful tool. and the 3-D graphics output plot truly is superb. This program by Arie far outshines some commercial antenna modelling programs costing upwards of 400 dollars.

If you use insulated wire for the antenna, just tie the nylon to the wire. Anymore, insulated wire is all I use for my antennas cause Home Depot doesn't sell bare wire small enough. I prefer #18-#20 insulated and stranded (not avail. at HD either). They do have #14.

==========

Anything will work!

To summarise, begining with 1 radial, all you can do is keep laying more radials until performance ceases to improve. Then that's the best which can be done at your QTH. Performance can be judged by measuring the strength of fixed, stable, not too distant, MF and lower frequency HF radio stations in daylight. There's an effect known as "Reciprocity" which means that an antenna with its ground system is just as good or bad on transmit as it is on receive.

If you increase the number of shallow-buried radials by 50 percent and there's no noticeable improvement then stop laying. Depending on the type of soil you will end up with a number which, in general, will be fewer than what you thought of before you started.

With a vertical, much depends on the lowest frequency of interest. Opinions differ but in my opinion, in average garden soil, there's not much point in laying shallow buried radials longer than 1/10th of a wavelength. They can be shorter in very fertile, fine, damp soil and longer in dry sandy or rocky soil. Fertility is the key. Increase their number according to the above 50 percent guidline.

Layout and bends in the wires are unimportant as are varying lengths. Just spread them out fairly uniformly over the area available. A 180-degree missing sector because the house gets in the way is not of great consequence.

Wire diameter has little electrical effect. Choose wire diameter according to type of soil and wire durability.

Forget about ground rods. A ground rod is little better electrically than a horizontal radial of about the same length. A short ground rod can be used as a common connecting point.

If you like amusing yourself with numbers, and for crude predictions of what to expect, download programs EARTHRES and RADIALS2 from website below. A little knowledge of your local soil resistivity can add much to the interest and help you to forget the lumbago.

Here is a data point for you. Instead of a tuner, I vary the length of
my "450 ohm" ladder-line to achieve a match at the current maximum
point. In very wet weather, I have seen a two-foot shift in the length
of ladder-line required on 40m from the dry length. 2 feet on 40m is
less than 2% of a wavelength. So I would say the difference between
wet and dry with ladder-line is less than the difference between
insulated and bare wire unless, of course, you lay your ladder-line
on a wet deck and deliberately coat it with soapy water.

Mark Sheffield, N0LF wrote:
"When I`m putting in an RF ground for either my station or for an antenna system, how do I know when I`ve achieved "good enough"?"

Measurement accuracy is sometimes overestimated as Reg Edwards, G4FGQ has often declared in this group. But, you know your RF ground is good enough when expanding the system brings very little improvement.

You need no RF ground for a properly balanced antenna system. For an unbalanced antenna, the ground system is 1/2 of the total antenna system. This system has a total resistance that is the sum of its desired radiation resistance and its undesired loss resistance. Nearly all the undesired loss is in the ground system. So, it`s very important to minimize ground loss in an unbalanced antenna system.

There are two ways to determine that you`ve rid your unbalanced antenna system of loss resistance. If the loss resistance is zero, the driving impedance of the 1/4-wave monopole against ground should measure 36.5 ohms (from 1950 Kraus "Antennas" page 315).

The second way is to measure the field intensity along the earth`s surface at a distance of one mile from the antenna. With 1 watt into the antenna, the field intensity at one mile is 6.5 millivolts/meter with a lossless system (from Kraus as above).

Best regards, Richard Harrison, KB5WZI

Used 50 ft of the cheapest TV twinlead (300ohm) I could find because it was a
temporary test. The antenna worked so well that I left it up from 83 to 96
through all kinds of weather including harsh Alberta winters. I never
noticed any noticeable SWR changes with weather, and when I took it down
I saved the twinlead for future use -- it was as good as new!

I Used 50 ft of the cheapest TV twinlead (300ohm) I could find because it was
a
temporary test. The antenna worked so well that I left it up from 83 to 96
through all kinds of weather including harsh Alberta winters. I never
noticed any noticeable SWR changes with weather, and when I took it down
I saved the twinlead for future use -- it was as good as new!
Bon Chance!

I should have mentioned. When measuring signal strengths as a measure of performance there's safety in numbers. Take the average of a fair number of transmissions, all well above the noise level, at about the same time each day, using your most stable S-meter with the receiver gain turned down such that the meter deflection is on the most sensitive sector of its scale. Allow the receiver to warm up for the same length of time on each occasion it is used.

S-meter calibration doesn't matter two hoots.

And once set, don't ever touch the receiver gain control.

You should take all these precautions from the time when you have laid only one radial. You will not wish to dig up already laid radials in order to re-measure the earlier ones you forgot to treat in the standard manner.

It will be appreciated, to make tests during radial-laying operations by asking for signal strength reports from your many friends, using THEIR S-meters, will result in you losing them.

Incidentally, when "I" used this method of testing antenna efficiency I stopped at 8, 10 feet, radials with a 3 feet rod at the end of each. This included the domestic incoming main water pipe which made no difference when THAT was connected. So I stopped.

But my soil resistivity is only about 70 ohm-metres. I can grow anything in my garden. At present it is covered with a dense growth of 3 feet high weeds except for a small patch which I use to feed the birds. As if they didn't get enough to eat anyhow. With the trees and overgrown bushes it is a wild-life sanctuary for frogs, rats, squirrels and hedgehogs. The only complaints I get are from the neighbours. But its stopped them complaining about TVI.

"You can stay the night in the Hotel Waldorf or the Hotel Lancaster in the Retiro and shop at Kelly`s-"

I usually stayed at the Claridge just off the pedestrian shopping street La Calle Florida. The company installed me there on my first arrival in Buenos Aires as I had no preference. When I returned there after a 6 month absence and was joyfully greeted by my name from the doorman. I was hooked.

On one of my 6 month tours in Argentina, I decided to give the Sussex Hotel across the street from the Claridge a try as all the oil field hands seemed to stay there. I arrived out of cigarettes, dying for a smoke, and asked the desk clerk if the Sussex had a smoke shop. When the clerk said no, I told him to send my luggage on up to my room while I shopped for cigarettes.

The clerk spyed me when I re-entered the hotel and called me over to give me a message from my wife who was very eager to see me. I thanked him although at that time I`d never been married, but I had discovered the main attraction of the Sussex Hotel! And they say a gringo is no damn good when he speaks Spanish!

I have a question similar to but different from the one posted a few lines below. How do you determine the quality of an antenna ground at HF on an absolute basis? Not how well have I maximized what Mother Nature gave me at my QTH by adding radials, but how good is my ground compared to other stations' grounds at other locations? I have read about the advantages of seawater, ground conductivity etc as guidelines, but how is overall ground quality (not just soil resistivity) determined objectively if indeed that is possible at all?

Hi George,

You compare a measured value with the theoretical, the difference is
loss. Less loss = better (objective goal expressed subjectively).

To state the objective goal objectively, you describe the difference
in dB. However, this quickly devolves to a subjective test, because
only your contact can appreciate the difference, and too often the
difference is less than many other factors of variability (like
fading).

So, let's put this in objective terms. With a dozen radials down, you
could double or quadruple that to achieve 2dB more power out. 2dB on
the conventional S-Meter may barely register more than a needle's
width change while your signal is otherwise dropping and rising 10dB
through a QSO. Go the limit (theoretical of course) of 120 radials
and you perhaps achieve 3 to 4 dB or two needle's widths.

Another objective test is to measure the resistance and compare it to
theoretical. However, take care to observe that theory covers a lot
of ground (no pun) principally depending upon the thickness of the
radiator. To take a useful and common indicator, that value would be
36 Ohms. If you measured 50 Ohms, the excess 14 Ohms could be thought
to be residing in poor connections and the loss of ground. You would
then tighten connections and add radials to shield against ground
loss. Hence by these actions, resistance would lower, and oddly (that
is, in contradiction to misguided expectations) SWR would rise. It is
unlikely you will add enough radials to achieve theoretical, but close
enough counts in RF, hand grenades, and H-Bombs.

It is called the law of diminishing returns (a business concept) where
the more you put into the ground is not matched in continued, improved
performance. It is the first few that count the most.

Not at HF, efficiently, because the ground penetration depth decreases for an RF wave as frequency increases. It is "skin effect" which decreases the depth with the square root of the frequency.

A steel well casing may make a good ground return at LF but not at HF.

A low-resistance ground connection for a transmit antenna is important to the received signal level only when the antenna design requires it as a reference for its driven element, such as with the vertical radiators used in MW broadcasting.

Most HF/VHF/UHF transmit antennas do not need, or use an earth ground for efficient radiation. As practical proof of this, recall that airborne antennas have no connection at all to earth ground, but still work just fine. And the transmit antennas used in commercial FM & TV broadcast are installed at the top of a tall tower, many wavelengths (and ohms) above earth potential. The tower is grounded for safety reasons, but the radiation patterns and received signal levels from those antennas would be the same even if that tower was not grounded.

George:

There is a published, and generally accepted method for measurement of complex impedance of earth, using standard lab instruments. I think it is in one of the CCIR publications, but don't have time to go dig it out at this moment. However, there are many radio engineers who will (likely correctly) question just how closely the results of these measurements reflect actual performance for an antenna site. One immediately evident reason is that the earth at the first reflection point may make more difference in the propagated signal at any given elevation angle than the characteristics immediately under the antenna.

==========

The performance of a ground electrode system cannot be separated from that of an associated antenna. But at least the antenna can be standardised by assuming it to be a simple vertical of given height. And we won't go far wrong by assuming the antenna efficiency to be 100 percent.

Engineering Quality is a numerical measure of how well something serves its intended purpose.

Since the purpose of a ground + antenna system is to radiate em waves the only possible numerical measure of Quality is radiating power efficiency measured as a percentage.

With beautiful and fortunate simplicity, the radiating efficiency of such a system is given by -

Eff = Rrad / (Rrad + Rloss) times 100%.

where Rrad is the antenna's radiation resistance looking into the base of the antenna, and Rloss is the resistance looking into the focal point of the ground electrode system, immediately under the antenna, such as a set of radial wires. Or it may be a single rod.

It is impossible to separately measure Rrad and Rloss. But Rrad can be calculated from the antenna's height and diameter and the two can be measured together. From the combined single measurement the efficiency can easily be calculated.

And that's where we part company with simplicity.

To calculate your "Quality on an absolute basis" of just the single ground rod involves a list of numerical variables as long as your arm. To calculate Quality of a system of radials imposes an impossible, intractible problem in statistics.

To compare one system with another would involve everybody with several lifetimes of fundamental research, measurement and guesswork which would get nobody anywhere.

However, because radio is by far the most inexact of all the engineering sciences, it doesn't matter a toss. All measurements are subject to error. In most of which even the standard deviations can only be guessed at. When will the next flare occur on our unstable Sun?

Radio engineers are quite accustomed to allowing safety margins of plus or minus 15 or 20 dB along propagation paths. Even then distortion and error rates are quoted. Brute force and ignorance and a lot of luck prevail.

So it doesn't matter whether or not Rloss lies between 1 and 10 ohms when used with your top-band inverted-L and you havn't the foggiest idea what the soil resistivity is in YOUR back yard.

Incidentally, ground loss is not only smaller in sea water, it is also smaller with soil resistivities of several thousand ohms and greater. There's a maximum somewhere in between.

To crudely estimate ground loss, download program RADIALS2 from website below. It's all crammed into only 70 kilo-bytes. Nobody has yet complained it gives the wrong answers.

Unless we have bad harmonics way up on microwaves, it should not. Looks like NYC already has WiFi distribution, you can see WiFi Hotspot antennas on the top of the public phone booths.

> But in practical terms, how do you get a "perfect" earth ground reference
> for the analyzer to use when making the measurement?
>
==========

You don't need a "perfect earth" because that is precisely the quantity you are trying to measure.

The only "perfect" thing is the 36 ohms which is the calculated value of the 1/4-wave antenna's radiation resistance.

But it is not essential to have an antenna as tall as a quarterwave to find the earth-loss resistance. There's not many people who can erect a 1/4-wave vertical at 160 meters.

The 'perfect' radiation resistance of an antenna shorter than 1/4-wave is given with sufficient accuracy by -

Rrad = Square(24 * Height / Wavelength) ohms.

Of course, an antenna shorter than 1/4-wave has reactance. But this can be tuned out with any coil which has a negligible loss resistance compared with antenna resistance.

Make the measurement at the resonant frequency of coil + antenna whatever it may be. The antenna analyser will tell you when you are at resonance. Vary frequency for the minimum pure resistance. And that is the resistance you are looking for.

The lower the measurement frequency the more easy and accurate the measurement provided it is not overdone. The earth resistance measurement doesn't have to be made at the same frequency the antenna is to be used at. It can be appreciably lower.

The great advantage of these one-hand held, battery-driven, antenna analysers is that the connecting wires can be kept very short, ie., much shorter than a 1/4-wavelength.

They are sufficiently accurate for this sort of job. And don't be afraid of lying on your belly to read the meter. The best things since sliced bread.

Reg, G4FGQ.

==========

It's not the UHF frequency of the very local mini transmitters which cause
the interference.

It is the broadband signals which come in via the phone wires between
computer and the local telephone exchange. They mostly affect the 160 and 80
meter bands.

This would cause US to interfere with the computers.

"Each would be capable of communicating with the wireless networking cards
that now come standard with many computers. "

Isn't this all 802.11 which is up at 2+ GHz and above?

Hi George,

The statement above falls into the category of "Old Wives' Tales."
Given the choice for conductors, Sea Water ranks 6 or 7 orders of
magnitude in worse conductivity than any metal (or even carbon) you
would care to pick. By this logic, you should do everything in your
power to operate in an open pit coal mine. ;-)

We won't go into the egregious error of soil resistivity for the same
reasons of senior matriarchal fabrications.

The "legendary" characteristic of Sea Water is found in its far field
reflective characteristic which is remarkable, due largely to its huge
SWR to fields (the same SWR that would occur with the supposed several
thousand ohms of soil). That small boats use a patch on the bottom of
the keel to offer a counterpoise to RF simply exhibits how little
ground development is necessary when the huge asset of reflectivity
dominates this large loss of a poor ground connection (you should also
note the ironic application of "ground" in this regard).

>To crudely estimate ground loss, download program RADIALS2 from website
>below. It's all crammed into only 70 kilo-bytes. Nobody has yet complained
>it gives the wrong answers.

For that matter, no one has even offered it works! Principally
because it places the onus on you proving one of two things:
1. it does work;
2. it does not work.
How can you tell? ;-)

You would stand a better chance with such forecasts using the old
Magic 8-Ball which would at least offer the occasional honest answer
like "Can't answer right now, try again."

Punchinello,

So, old man, tell us when you are going to offer any substantive
method that gives numbers to these illusions of ground you offer? The
soil of your back garden, much less Britain hardly are representative
of a much greater continental expanses beyond that little island you

occupy. The examples of your erroneous generalizations against reality would be instructive if you simply expanded (embarrassingly perhaps) on your kitchen calculations of mud calibration. After all, its been simply YEARS since you offered such suggestions to no obvious Kelvinian payoff.

How does the statement above reconcile with the fact that groundwave daytime signal strength is far better over a sea water path than any ground path? There is (essentially) no returning skywave signal to reflect during daylight hours.

Observe the daytime field strength contours shown on the link below for WABC radio, for example.

So you are saying that sea water paths provide far better groundwave
propagation than overland paths because sea water a such a good reflector?

Yes, a wave striking the sea finds a high reflection coefficient and ground waves do well too.

I am looking at a broadcast allocation book prepared by Cleveland Institute of Radio Electronics in 1959. Many changes in stations and coverage since then, but the book contains an estimated ground conductivity map for the U.S.A. which probably has changed very little since then.

Coastal Texas is almost as good as it gets when it comes to soil on the map, 30 millimhos per meter. Seawater is not shown on the map but its conductivity is given as 5,000 millimhos per meter or 167 times as good as the best soil. Around New York City, conductivity is shown between 0.5 and 4 millimhos. Surface irregularities caused by structures make additional attenuation.

The conductivities shown on the map are probably good averages as the preparers had the propagation data of thousands of broadcast stations which proved their performance to the FCC to work with.

Terman has a ground constant table on page 808 of his 1955 of his 1955 edition. Sea water is given a conductivity of 45,000 micromhos per cm, or 45 millimhos per cm.

John Cunningham says in "The Complete Broadcast Antenna Handbook: on page 309 that:
"The conductivity of the earth ranges from about 2 millimhos per meter for dry sandy locations to as high as 5 mhos/m for sea water."

I think the figures given above are in reasonable agreement. I haven`t researched the conductivity of carbon, but it is reasonably high being used for motor brushes, battery electrodes, and vacuum tube plates.

Best regards, Richard Harrison, KB5WZI

That it isn't the reflective nature of sea water that is responsible for its good propagation of groundwave signals. That is due to its conductivity.

Hi Richard,

If all would review the standard FCC groundwave propagation curves, they would notice that they offer low AM Band signal strengths in terms of "conductivity" and that the differences in strength for the 5,000 millimhos per meter and that of 40 millimhos per meter (125 fold difference) DO NOT achieve the same proportional difference in received signal strength. In fact, the difference is so narrow you could shave with a razor as sharp as it. Even at the high end of the band the difference has to be out 700 miles to show the "conductive" ratio. Of course, over that range of transmission ONLY Sea Water would support that forecast as continental soil varies vastly in smaller spans - hence the reputation of the Sea.

>John Cunningham says in "The Complete Broadcast Antenna Handbook: on >page 309 that:
>"The conductivity of the earth ranges from about 2 millimhos per meter >for dry sandy locations to as high as 5 mhos/m for sea water."

This is the conundrum of conductivity of earth: that there is so much contradiction. You cite coastal Texas, but in distinct contradiction to the dry sandy locations forecasts, pan handle Texas also exhibits just as high conductivities for less water as Corpus Christi which oddly enough easily has twice the sand content as those arid wastelands.

There are a lot of reductionist statements about ground that simply don't exhibit against the claims made for it. Reggie has long claimed to be an authority on the subject, and when push comes to shove for my hints that he offer Kelvinian substance, he complains about the CIA or his insufficient understanding of English. The urchins of Rio would guffaw at that one. I will anticipate Punchinello's Magic 8-Ball answer "try again later," as I am sure the software could do no better. ;-)

And by the way, the kitchen calibration of mud is a common gardener's exercise, why Punchinello cannot or does not recite it is evidence that no one really cares to ask (me or him). His embarrassment would be found in its lack of correlation to RF (there are far more

variables to consider).

For a reality check, here are the approx distances to the 1 mV/m contour for 1kW of radiated power from a 90 degree vertical with a good radial ground system. The values were determined from the FCC's standard curves.

Freq Conductivity/Miles

540 kHz 8/66, 40/124, 5,000/140
1,600 kHz 8/22, 40/56, 5,000/126

The average ground conductivity in the U.S. is fairly low, probably somewhere between 8 and 16 mS/m. The difference in ground wave propagation over such paths is dramatically poorer than over sea water.

It is also clear from the above values how much better the low freq MW broadcast channels perform.

Of the software that is available for purchase for a reasonable price
(less than $200):

1. EZNEC 4.0

2. NEC-Win Plus

3. Antenna Model

is there a general consensus of the best of these?

Is it worth paying more for some of the features, e.g., EZNEC/4 for $600?

Are there others that are preferred?

What about free versions of the NEC code?

I am interested in modeling a helically wound antenna and so need a lot
of segments.

Thanks.

It's not an "old wives' tale" at all.

We have to remember that there are two loss mechanisms involved with antennas. One is the resistance encountered by ground current flowing to one of the feedline terminals in a ground-mounted antenna. This can be reduced to an arbitrarily small value by installing radials. The other is loss incurred when the field strikes the ground and reflects. This second loss is generally negligible for horizontally polarized antennas except at high radiation angles, but is very significant for verticals at low angles. This loss occurs mainly beyond the far edge of most radial fields, so there's usually nothing you can do to reduce the reflection loss except to move the antenna.

Perfectly conducting ground has no loss, and perfectly insulating ground has no loss. When considering ground system loss (resistance encountered by local ground currents), the loss is maximum somewhere in between. Doing some experimental modeling with EZNEC/4 (NEC-4 based), I've found that the maximum loss for a radial ground system in the HF range unfortunately hits somewhere around average soil conductivity. It's not an abrupt maximum -- the loss varies fairly gently with conductivity.

Reflection loss has to be considered a little differently. While the same statement about perfectly conducting and perfectly insulating ground is still true, if you had perfectly insulating ground, radiated power would be lost to useful radiation by penetrating the ground, whether or not it got dissipated as heat. (In reality, it would of

course eventually get dissipated, since no ground is perfectly insulating.) Looking just at the amount of radiation that ends up above the horizon, and neglecting conductive ground current loss, the reflection "loss" does indeed seem to increase monotonically as the ground conductivity decreases.

The ground reflection loss can easily be evaluated with any version of EZNEC, including the demo. Choose a vertical antenna such as example file Vert1.ez, set the ground type to Real/MININEC, wire loss to zero, and the plot type to 3D. There should be no resistive loads in the model. Then look at the Average Gain shown at the bottom of the main window after doing a plot calculation. The deviation from a value of 1 (0 dB) represents the fraction of the applied power that's lost in the ground reflection.

I couldn't resist the temptation to copy the following messages from the UK newsgroup.

==========

> >The so-called swr meter is no more and no less than a simple RF resistance
> >bridge which is either balanced or unbalanced. Usually the latter.
> >
>
> Reg,
> I know you 'have a thing' about the SWR meter not measuring SWR.
> I have an ohm-meter. It doesn't 'measure' ohms. It actually measures current.
> How many 'meters' actually measure what we say they measure?
> Speedometer?
> Flow-meter?
> Odometer?
> Kill-ommeter? (as pronounced by thickies - ugh!)
> Methinks thou splitteth hairs.
> Ian.

==========

The current which is 'measured' by an ohmeter actually exists.

Yet another reason why the so-called swr meter does not measure swr is because there is no transmission line (between meter and transmitter) on which to measure it. SWR on it cannot not exist.

Ian, without wishing to cause the slightest offence, I'm afraid your long, ingrained, aquaintance with the old-wives' tales surrounding swr meters is preventing you (and others) from seeing things from a different point of view.

The instrument is just a 4-arm RF resistance bridge, the arm subject to variation being the input impedance of the transmission line to the antenna which can be any Zo you like. The other 3 arms are fixed.

The 'meter' merely indicates whether or not the input impedance of the line-to-the-antenna is some special value of ohms (usually 50) because that is the desired transmitter load.

It won't, and cannot even, tell you what the value of that special value actually is except under the very exceptional condition that it is exactly correct.

And it tells you absolutely nothing else about what exists or is going on in the station unless you deduce and add to it what you already know by other means anyway.

My objection to current practice arises because the invalid name of the instrument, plus all the arguments which arise in futile attempts to justify it, cause nothing but emotional confusion amongst novices and old-wives alike.

So why not just change the name to TLI (Transmitter Loading Indicator) and all the confusion and arguments will cease. Novices will no longer have to be re-educated about the true meaning and relevance of swr.

Or YOU can choose a new name if you wish and take the credit for it.

No circuit changes are needed. ;o)

Regards, Reg, G4FGQ

Adam,
I don't have the articles, though I do remember them. However, the
site below shows the same antennas as I recall in the article and may
be of use to you. The site is authored by Kent Brtain, shows pictures,
has tables showing dimensions from 2 meters to 1.2 gig and may even
have more info than was in the articles.

The consensus of opinion over on science.physics.electromag is
that a two foot long section of 50 ohm coax is all the length
needed to force the V/I ratio to be 50 ohms at HF - something
to do with the length Vs separation between conductors ratio.
That V/I ratio = 50 is the assumption made by the SWR meter
designer when the meter is calibrated.

2716. twinlead question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-09-03 03:47:07 UTC
From: pdrunen@aol.com
Message-ID: <20040902234707.08241.00000029@mb-m10.aol.com>
Source record: 90037

Hi again Group,

Thanks again for the help with the other questions I have posted on the board.

Does anyone know the hurricane net frequency? Next few days should be interesting for me, I am near Pensacola so I may not see as much action.

For my question on twinlead, most folks now use the 300:75 ohm balun at the TV antenna and drive coax down to the TV set. Has any one measured the impedance at the set with the MFJ-269 or equal over the range of TV channel 2 to 13? and 14 to 69?

I recall working for a TV service man back in the 80's (I was a ham teen). He would put a twist on the feeder as he brough it down the pole and used 6 inch standoffs to keep the line from getting near the metal pole and to keep it straight. He used only RCA antenna's and gave me my first digital VOM for my birthday. I still have it today. I believe he enjoyed having a techie teen around who enjoyed the concept of the ether.

Could we get away from the above by placing a metal shield around the twin-lead or would this effect the impedance of the twin-lead? My goal is a folded dipole and use the 300 ohm twin-lead with an outer shield to keep coupling from metal out of the equation.

Well, all for now.

73's from KJ4UO.....

You most certainly will see some action, if Hurricane Frances follows the current forecast track and comes right across the Florida Panhandle! HWN is 14.325.0 USB. Not very active after 0100-0200z. Other freqs put out there today were 7.247, corrected to 7.242, did not seem to know what they were talking about there, and 3.950, both presumably LSB. 3.950 LSB is active now.

Someone else will have to help on your question about vhf-2 to vhf-13 impedance. The only time I receive broadcast tv is during hurricanes when the cable is out. You might be there soon, I'm thnking. Good luck and stay safe.

2718. Cell Phone Hardline

Newsgroup: rec.radio.amateur.antenna
Date: 2004-09-03 04:28:05 UTC
From: theplanters95@aol.comnospam
Message-ID: <20040903002805.25434.00000024@mb-m04.aol.com>
Source record: 90039

I have an offer to purchase some used hardline from a cell phone system. Is it suitable for use on 2m? Can it be run over a shingle roof or does it need standoffs? What is a good price for 100 feet with N Connectors?

Here is the email that I received.

It is previously used and not new. If you feel it is worth somthing to you, make up a price. I will see if I can find a another N-Female connector to go on the other end. Posibly another N-Female for the open end. Most of the Hard Line is from Cell Phone towers that are getting up graded to a new lower loss feed line. Cell Swept Hard Line is more expensive than standard run of the mill. Some Pieces have a ground wire on them and a strain relif for hoisting up the tower (Finger Pusle grip lock).

For free packages, I find the 4nec2 program amongst the most powerful
and easy to use. You can download it from the NEC Archives at
http://www.qsl.net/wb6tpu/swindex.html

It has most, if not all, of the features of many of the commercial
packages plus a few that they don't have. I believe the NEC2 engine
underlying the gui is set up to handle up to 11,000 segments.

Recommend never buying used feedline, for any reason. If it's free, and you
don't find it perforated a million places from lightning, give it a try.
Otherwise the most it's worth is it's scrap value in copper, less the cost
of stripping the dialectric, shield and covering.

> -Ray WB6TPU

Can confirm all that Ray says. 4nec2 is an outstanding program that is
constantly having new features added. The 3-D viewer is spectacular and
generates 21 shades of colour denoting gain in dBi superimposed over
antenna structure. Rotates in 3 dimentions.

Has Optimizer for SWR, Gain, F/B, F/R, input resistance and input reactance.

You can specify insulated wire. Arie supplies 25 different coatings.

Has standard .nec input and output file format so unlimited amount of
antenna designs can be studied. Entry level commercial programs have each
their own unique file format so tying you into their system.

Has Geometry Builder so if you wish you can graphically input your new
antenna.

And as Ray said 11,000 segments and patches.

Much, much more.

Download 4nec2X and you will get the realtime 3D viewer.

Arie is to be congratulated on making his program freely available.

Of course, this is only true (in the practical sense) for that brief interval until any reflections arrive back at the point where the measurements are being made and all hell breaks loose. It is very obviously all tied into the meaning of 'characteristic impedance' - there's no mystery here.

Semantics.

There is often miscommunication(*) about the distinction between the initial period (before the reflections arrive) and the steady state mess that arises further along the time axis.

*These can be easily identified - even defined - as any thread that includes more than about 20 postings by Cecil. ;-)

The indication displayed by that meter is the result of the match of the transmission line and antenna connected to the output of the transmitter to the value for which the meter was designed and calibrated. Certainly it is possible for SWR to exist in this RF system in normal use, and the meter measures its value.

> My objection to current practice arises because the invalid
>name of the instrument, plus all the arguments which arise
>in futile attempts to justify it, cause nothing but emotional
>confusion amongst novices and old-wives alike.

The generic function of this meter is to measure the degree of match between a source and a load. It is not a direct measure of SWR. When properly designed, it is a measure and comparison of voltages developed by the incident and reflected power in the system as they pass a sample point.

There may not be enough transmission line in the RF system for the standing wave pattern itself to develop on it fully. It doesn't matter. The ratio of forward to reflected power in the system will be the same as if there WAS enough line, and that is what the meter measures.

The meter could be calibrated in units of return loss, reflection coefficient, or SWR -- all of which have corresponding equivalents. A return loss of 26.45 dB = 4.76% reflection coefficient = 1.1:1 SWR, for example.

The historical convention for this meter is to calibrate its display in units of SWR. Or the meter scale could just have three zones: Good - ? - Bad, which would do away with all these troublesome technical terms and the objections they elicit from some (nudge, nudge). No offense.

RF

OK, Reg, when the conductors are 1/4 inch apart, what length
of coax is necessary for the Z0 of the coax to effect the
ratio of E-field to H-field? Those pretty smart guys over
on s.p.e say a ratio of 100:1 length/separation is plenty
enough to force the V/I ratio to be 50 ohms.

We can actually measure the V/I ratio at the input to the
SWR meter. I'll bet, when a properly calibrated 50 ohm SWR
meter is reading zero reflected power, that the V/I ratio
is indeed 50 ohms.

Exactly! So let's call it a TLI. Which is what it actually is. Abolish
the source of confusion and the arguments on what it does.

Of what use is the swr to anybody anyway, even when you think you know what
it is? What do you do with it? What does it tell you that you don't
already know?

Reg

Unless it has succumbed to water damage or lightning, you should have no problem with it. The insertion loss will be very low on 2M compared to other (new) options at the same price.

I use both new and used cable, and it is very rare that I find a piece of used hardline that has unacceptable insertion loss.

Usually the problems arise at the connector, rather than the (hardline) cable length itself.

"---a two foot long section of 50 ohm coax is all the length needed to force the V/I ratio to be 50 ohms at HF---"

At 3 MHz?

When power is applied to a transmission line, energy from the power source doesn`t appear everywhere along the line at once. Instead, energy travels away from the source in the form of an EM wave called the "incident wave" arriving at various spots along the line in order and at sequential times.The time it takes to travel through each line segment depends on the four properties of the line, series resistance (R), series inductance (L), shunt capacitance (C), and shunt conductance (G).

Source current will start charging the shunt capacitance of the first line segment. It is delayed by the series inductance and resistance of the first segment. Resistance does not directly delay current, but limits current to the capacitace. As the shunt capacitance is charged, the charging current tapers, but the next line segment starts charging through its series inductance and resisitance. This energy travel process continues sequentially throughout the line.

The value of current in an infinite line is the line voltage divided by the line`s Zo. In a line with reflection, the current in each direction is the voltage motivating the current in thet direction divided by Zo.

Just how short can a transmission line be and still enforce its Zo? A 1/4-wave matching section inverts impedance between its ends by enforcing its Zo.

For Zo to equal the square root of L/C, (a resistance), XL must be much greater than R, and XC must be much greater than G. These restrictions impose frequency limits on Zo. And, these restrictions may place a low frequency limit on how short a line can be and still enforce Zo.

Best regards, Richard Harrison, KB5WZI

You strive to minimize it.

>What does it tell you that you don't already know?

You won't know anything about the degree of match between a source and its load without a means of measuring it. It doesn't matter whether we state the result of the measurement in units of SWR, return loss or as a reflection coefficient -- they all give the same information, and allow the same action to be taken as a result.

To be accurate and valid, none of these units requires measurements to be taken with some discrete length of transmission line between the source and the load -- including SWR.

For a concept of what that length actually is in the real world, recall that Bird Corp and others supply directional wattmeters giving reasonably accurate measurement of forward and reflected power -- leading to an SWR value. The coax sampling sections for RF frequencies at least as low as 540 kHz. is around 9" in length.

Does the "MICE" connection on an Icom radio suppose to go to the shield on
the microphone. That is the way my microphone is wired. I would have thought
the shield is suppose to go to ground. Maybe MICE means mic earth.

Afterthought... if you call it a TLI, is that really less confusing? The term "Transmitter Loading Indicator" could apply to a way to display the amount of power at the tx output terminals, and show nothing of the quality of the load that is dissipating that power (e.g., the degree of match between the source and the load).

Sounds a little like my counterpoise. 12 wires 12ft long, Short ground rod at far end of each wire just to pin it down. 10ft 2inch pipe in the middle for ground/ mount. You can get an idea of resistance to ground by connecting 120 VAC to the ground system through a fuse and see how big of a fuse you can blow. I rigged a fuse holder with a neon blown fuse indicator to a piece of PVC pipe. last time I checked mine it would pop a 10amp fuse.

Reg,

I'm afraid you're wasting your time trying to convince mere amateurs with your carefully reasoned and flawless logic.

Instead, I suggest you concentrate your efforts on the true professionals out there. Surely, they'll immediately see the wisdom of your arguments and change their careless ways.

I'm talking of course about the engineers in such unenlightened companies as HP/Agilent, Narda, Tektronix, Wiltron/Anritsu, and their colleagues and competitors in the U.K. They're constantly making the same egregious error, by specifying the SWR of terminating resistors, connectors, test equipment device inputs, and even (gasp) outputs.

Once the professionals change their ways, amateurs, copycats as they are, will surely follow.

Good luck with your quest!

Roy Lewallen, W7EL

"SWR" has two different definitions, and Cecil is switching between them with his usual facility.

Definition 1: the ratio of maximum to minimum voltage on a transmission line. To measure that, you obviously need a significant length of transmission line "for the wave to stand on" - depending on there the maximum and minimum are, you could need anything between an electrical quarter-wave or an electrical half-wave to locate both points with certainty.

Cecil wrote:
>
>The consensus of opinion over on science.physics.electromag is
>that a two foot long section of 50 ohm coax is all the length
>needed to force the V/I ratio to be 50 ohms at HF - something
>to do with the length Vs separation between conductors ratio.

This is a side-issue, not relevant to the main discussion. I'm not sure whether that distance should be in units of wavelengths, line diameters or a function of both - but definitely not a simple length in feet or metres. However, the line length required for the V/I ratio to come very close to its characteristic value is certainly a lot less than the length required to measure an SWR under Definition 1, so it's a completely separate side-issue.

Cecil again:
>That V/I ratio = 50 is the assumption made by the SWR meter
>designer when the meter is calibrated.

That *is* relevant - but it's relevant to a different definition of SWR!

Definition 2: a mathematical function indicating how closely a given impedance is matched to a given system reference impedance.

Under definition 2, you can measure SWR at a single point in the line. The "given impedance" whose SWR you are measuring is the impedance connected to the Output (or "Antenna", or "Load") side of the meter. If 50 ohms is the chosen system reference impedance, then the SWR meter is designed, built and calibrated to indicate SWR=1 when it's terminated in an accurate load of that impedance.

Everybody lives very comfortably with those two definitions of "SWR" that exist side by side.

And that includes Reg - he understands transmission lines inside-out, and two definitions of "SWR" don't trouble him in the slightest.

What Reg can't live with is that uncontrollable itch to make people jump through hoops.

Randy,

It can not hurt to look at the feedline - it would be a good idea to find
out the size you are dealing with 1/2" ; 3/4"; 7/8"; 1" etc.
The traditional cellular (AMPS) frequency allocation is 800 MHz - 900 MHz.

The Personal Communications Service or PCS -- which is at 1.8 - 2.0 GHz was
established by the FCC
in 1984, with auctions of the spectrum in 1985. Each auction allowed 2 or 3
primary bidders for spectrum for each major
geographical area of the US. Sprint Spectrum (now known as Sprint PCS)
acquired primary allocations for 95% of these
areas.

True, and these work with mismatched loads if you have enough 50-ohm cable connecting the wattmeter.

The Bird Model 43 wattmeter is 5.125 inches (13 cm) wide. This is the distance between its input and output connectors. This length of "high precision 50 ohm coaxial air line designed for insertion between the transmitter or load" requires either some more 50-ohm line or a matched load to enforce Zo.

IF you were to insert the Model 43 into most 75-ohm transmission systems, the precision 50-ohm meter line of 5.125 inches would not likely enforce the 50-ohm V/I ratio and the meter reading would be in error. At VHF, 1/2-wave of connecting line including the Model 43 wattmeter is ideal, allowing you to insert and withdraw the meter without affecting the match.

Best regards, Richard Harrison, KB5WZI

> > Speedometer?

So these used to measure magnetic drag on a conducting cup of a transmission output monitoring rotary cable and therefore should be called a Mdoaccoatomrc-o-meter

> > Flow-meter?

Lets see. One versions I am familiar with measures the number of free balls passing a given point in a circulary disposed tube while following the movement of a liquid and therefore is a:
Fbpagpiacdt-o-meter, I guess..

> > Odometer?
And this turky measures the revolutions of the first thingy.

> > Kill-ommeter? (as pronounced by thickies - ugh!)

Don't you mean Kill-o-meter?

Woops! Does anyone sell these meters???

Besides we say cent-a-meter

And... and... an ohm-meter is really an "incorrectly calibrated am-meter", as is a volt-meter. Then is an am-meter a "magnetic field produced by a coil", or an MFPBAC-o-meter ???

> > Methinks thou splitteth hairs.

Well...

How come we say ther-mom-eter and speed-om-eter and o-dom-eter and comp-tom-eter, but we don't say ohm-om-eter, volt-om-eter nor am-om-eter...

And how come we say "how come" when we mean "why do"????
And why is a "K" 1000 in our world and a "K" 1024 in the digital world except for hard drives where a meg is 1,000,000....

...and why am I here... for those who like rhetoricals.

Someone needs something serious to think/talk/post about.

Hmmmm. Me thinketh there needs to be a troll-o-meter, or would it be a troll-om-eter...
73

Boy! spell check sure didn't like this post!

Following is a list of coordination information for Amateur Radio and CERT Personnel who make the decision to evacuate the area. Upon return, after the storm has passed, Amateur Radio Operators and CERT personnel will stage at the Palm Bay BCC north Parking Lot for assignments. If the parking lot is inaccessible or unusable as a staging area. We will stage in the Bayside Lakes Publix Plaza parking lot near Beef O' Brady's.

For Amateur Radio Operators :

Below is a list of frequencies that can be used by amateur radio operators who evacuate the Melbourne/Palm Bay area to stay in touch. We will plan on making contact at 5:00 pm, 6:00pm, and 7:00 pm. on 14.340 MHz. In the event radio communication conditions are bad, try one of the other listed frequencies. We will use these as calling frequencies so once contact is made you and your other party may want to select another frequency to move to or you may wish to remain on frequency and join the group that will be on the frequency.

Operators that remain in the Melbourne/Palm Bay area may also use these frequencies to contact individuals that have departed the area for news etc. if things get slow.

When you return to the area after the storm has passed we will assume no repeaters are left standing and will coordinate our activities on 145.520 Simplex. A net may be established on 145.520 by the time you return. You may be directed by net control to move to a frequency that is not programmed in your radio. You may want to plan on having your radio operating manuals with you when you evacuate. Establishing communications will be our top priority when you return.

145.520 MHz Simplex
14.340 MHz Primary
21.415 MHz
28.335 MHz

If you know of an amateur that is planning on evacuating and is not in the distribution list or did receive this notice, please forward or give a copy

of this message to them Please print this list out and take it with you when you leave the area. Good Luck Stay Safe

Thank You
Steven Hathaway
South Brevard County Emergency Coordinator

"Richard Harrison"
> Just how short can a transmission line be
> and still enforce its Zo?

The whole thing is perfectly clear if one imagines applying a step function (rising edge) to any short, even VERY short, length of transmission line. The current in the short line will be equal to V/Zo - at least until the reflections (if any) start arriving back at the input. If the line happen to be terminated with Zo, then no reflections and I=V/Zo is the steady state.

The only issue of shortness is that a very short line means very short time until the reflections arrive.

The step function makes things a lot easier to understand than RF. It 'enforces' the distinction between the transient period and steady state.

This thread is of interest to me in that I like many others have antenna
programs in DOS
Now all computors sare sold with Windows XP which has no provision for dos
Now many programs shown on the given page are also written in DOS and
loosely
describe that it is to be used with a 32 bit console program mode. But there
does not seem to be any specifics
about this or where it can be obtained ,which leads me to think of
discarding all the newer window programs
and backtrack to Windows 98.
So for a newcomer it is not all that simple as compatability is not ensured
when one has a computor
that is four years old or newer.
It also begs the question why, as processors become faster ,one backtracks
by using "32 bits".
Thus the thread initiator has to step carefully to ensure that the program
chosen is compatable
and useable with XP program which now appears to be the choice of today, and
not have to tread though a
range of additional interface additions.

IMO, the length of the line is irrelevant when using a device such as the Bruene bridge or a Bird 43. Each of those instruments are designed or adjusted to indicate the forward or reflected power, based on three things: 1) ratio of the foward and reflected voltages, the voltage reflection coefficient 2) the scale numbered from 0 to 1, where 0 indicates the reflection is zero, and 1 equals total reflection, but the significant point is that a 3:1 mismatch gives a reflection coefficient of 0.5, which then means that the half-scale reading of 0.5 indicates the 3:1 mismatch, or a 3:1 SWR, and 3) the device is so designed or adjusted so that the voltage ratios indicate the correct value because it's inherent characteristic impedance, Zo, is 50 ohms.

Thus, no transmission line is necessary. For example, the device can be connected directly to the antenna terminals, or any other device you desire to determine the mismatch, and power it directly from the signal source--no transmission line is needed on either port for the device to indicate the degree of mismatch.

Yet a 50 ohm RF bridge or network analyzer with a 75 ohm termination applied directly at its output port has no trouble showing the true SWR. These measuring devices are looking at the same transition plane from 50 to 75 ohms as the Bird 43 would see with a 75 ohm load at its output port.

If the Model 43 is unable to make an accurate measurement of this, is that not due to reasons other than not having the right 50-ohm V/I ratio in its line section?

Don't have time to address all the issues with all the programs
available in the archives, but 4nec2 works just fine with both Win98 and
WinXP. It is a true Windows application (the actual NEC2 engine does
come up in a DOS window, but all user interaction is via Windows).

I use several DOS programs that run perfectly in XP. XP is based on
the NT Kernel, therefore, the 'DOS' that you actually see, is merely
an emulation. By right clicking the .exe, selecting Properties and
selecting Compatibility Mode under the Compatibility tab, you can
probably run most anything you want. At lease I have found this to be
the case.

80
> meter bands.
>
==========

But I hasten to add that nearby amateur radio stations, as well as MF and HF high-power broadcasting stations can interfere with ordinary broadband internet services.

Interference is likely to be intermiitent, or unregonised as such, So there are few ways of proving or dis-proving a particular source. It's a matter of random statistics.

The legal facts of the situation are that amateurs are licensed to transmit with a given transmitter power within precisely defined bands of frequencies which indeed they conscientiously adhere to. And internet services are not required to respond in any way whatsoever to such legal transmissions. If they do so respond or are affected by such legal transmissions then it can only be due to some weakness or fault in design or manufacture of their (the Internet) equipment affected.

In the none-too-distant future the quality of Internet sevices will depend entirely on the signal-to-interference ratios. The problem can ultimately be solved only by having light-fibres laid to everybody's front door. Which, of course, will be expensive.

Inevitably, Economics decided by the most-powerful of the multinationals will Rule. Unfotunately, so-called democratic governments will have very little say in the matter. As is already very apparent.

But us computer-owners are all so rich these days who cares about the details?

Let's think a little about the Iraquis, deprived of essential electricity, educational, medical, food, clean water, transport, police, social and hospital sevices, etc.

The Vietnamese and Cambodian victims of weapons of mass destruction, after 30 years, are gradually getting back to normal - apart, of course, from the genetically deformed and mentally deficient babies, the result of deliberate poisoning and bombing by a country which imagines itself, not unsurprisingly, to have international enemies.

i have a question.

in reference to station grounding, i have read keep the grounding strap as short as possible and not a multiple of a resonant length on the ham bands. with that in mind, even if i ground pieces of equipment to individual ground rods, won't the complete grounding system be long? in my mind i am looking around the room and seeing a grounding system being at least 12 feet long, if i go along the perimeter of the desks (which are in a "U" shape in the room.

trying to grasp this in a practical sense. sorry if it is basic and i am just not understanding it.

not responsible for spelling. :-) any input on this would be most appreciated.

|Exactly!

Not!

The source plays no role at all. The degree of match that is
indicated is that between the line (or system Zo) and the load Z.

A 50 ohm instrument with a 50 ohm termination shows a reflection
coefficient (or whatever mathematical equivalent you want to use) of
zero regardless of the source impedance.

|So let's call it a TLI.

Let's don't. That's just more bafflegab. Suppose the source impedance
is 25 ohm and the load is 50 ohm. By this new monstrosity of a
definition, the source should be delighted when the "transmitter
loading indicator" says---well---I'm not sure what it says, but I
think the desired number is either 0 or 1. And another source
(transmitter) with a source Z of 100 ohm should be equally happy.
Right?

|Which is what it actually is. Abolish
|the source of confusion and the arguments on what it does.

I'm all for abolishing the confusion too, so why did you add to it?

Hi Mike. "Single Point ground"...this means *not* daisy-chaining to a bus bar behind equipment tables if possible, and connecting each piece of equipment to one (1) point that becomes the station's single point ground. *Not* several ground rods from "individual" equipment. After you collect all the station bonding straps at a single point, then you run to a very close ground rod. After you hit that first single ground rod with the bus from all station equipment, *then* you can branch out in a wide and plentiful ground field that bonds to all your antenna, towers, masts, and last but definitely not least, a direct low impedance and high current capable bond to the main AC service ground rod of your home. The RF portion of the ground can accomodate parallel connections to multiple ground rods in close to the station if necessary. They must be part of the lightning protection ground, never separate from it. There are tons of resources for this and lots of experts here in this group. You can also try this website I built just for those questions...one of the pages addresses RF grounds from the transmitter.

OK, I follow all that; but it doesn't fully address the original poster's question about ground routing inside the operating room.

The question really is: what's the best *practical* way to route the grounding from that single exit point to all the individual pieces of equipment on the operating desks?

Even a small amateur station can be spread over several feet of desk; L-shaped corner layouts are very common; and the OP is talking about an even larger U-shaped layout. This means the distances from individual items of equipment to the common the ground exit point can range from a few feet up to even a few tens of feet (in terms of the minimum practical distance around the rear of the desks). Also, modern amateur stations are heavily cross-connected by signal/data/control cables, which provide additional paths for damaging current surges to get inside the equipment.

Everyone agrees (I hope) that the objective is to keep all the equipment at the same potential, even when the local ground potential "bounces" due to a nearby strike. Above all, the objective is to avoid current surges going through the insides of individual items - those are what do the damage.

For all the practical reasons outlined above, I don't believe there is a completely "right" answer to the grounding problem inside the operating room. Every practical method seems to have some drawbacks.

Based on your experience, what are your views about that specific problem, Jack?

The only difference between those two terms is that "match between" is normal and grammatical technical usage; and "match of" ain't neither.

Wes is correct. What the meter measures is the match (expressed as reflection coefficient, SWR, whatever) between the system Zo for which that meter was designed and calibrated, and the load Z.

The meter measures nothing that involves the source, except the level of RF that it supplies. It does not respond in any way whatever to the source impedance.

Not that I said it did in my part of the thread, but nevertheless the above statement is not strictly true. In the case where the source Z of the tx PA does not match its load Z (which is typical), power reflected from the load mismatch will at least partly be re-reflected from the PA -- which then contributes to the power sensed by a "wattmeter" in the output path.

You quote only a part of my post with which you happen to agree, and then say I find controversy when there is none.

The point of my last post on this subject, and our <<real>> controversy here relates to which characteristic of sea water is responsible for its lower groundwave path loss, as developed in the thread. You wrote that the reason is because sea water is a good reflector. I wrote that it is because of its good conductivity. This difference in our positions should be evident by reading the thread.

Unless your antenna requires an earth ground as an integral part of its design, the length or number of ham band wavelengths, or even the existence of a metallic path to earth is irrelevant to the radiation characteristics of the antenna itself.

Still, a good earth ground and other means are desirable to protect your equipment from lightning transients, as developed by Jack Painter on his informative website link earlier in this thread.

Here is a re-post of some earlier text I posted about the need for an "antenna ground."

GW asked (clip):
> How do you determine the quality of an antenna ground at HF
>on an absolute basis? Not how well have I maximized what
>Mother Nature gave me at my QTH by adding radials, but
>how good is my ground compared to other stations' grounds
>at other locations?

A low-resistance ground connection for a transmit antenna is important to the received signal level only when the antenna design requires it as a reference for its driven element, such as with the vertical radiators used in MW broadcasting.

Most HF/VHF/UHF transmit antennas do not need, or use an earth ground for efficient radiation. As practical proof of this, recall that airborne antennas have no connection at all to earth ground, but still work just fine.
And the transmit antennas used in commercial FM & TV broadcast are installed at the top of a tall tower, many wavelengths (and ohms) above earth potential. The tower is grounded for safety reasons, but the radiation patterns and received signal levels from those antennas would be the same even if that tower was not grounded.

free is a good price. anything more and you are paying to take out their garbage. connectors can be built for most hardlines from simple plumbing fittings and common connectors and adapters. it would run over a shingle roof just fine, you just want to make sure it doesn't flop around or it could wear on the shingles or rub through it's outer jacket.

'as short as possible' it the important phrase. its not always possible to keep it really short. another important part is keeping it as fat as possible, meaning use heavy wire or, even better, something like copper flashing, aluminum flashing or angle stock, or something like that. aluminum angle stock that you find in 6-8' lengths in hardware stores makes excellent ground busses, its easily drilled for connections to equipment, can be easily bolted together at corners, and makes a nice neat installtion... use the 1" or wider stuff if you can get it. do not use multiple ground rods unless you also connect them all together outside... and if you do drive a 'station' ground rod be sure it is also connected outside with heavy conductor to your existing power entrance ground. and while you are at it make sure the power entrance is also connected to your water pipe coming in, pool filter ground, outdoor light ground, and anything else grounded outside the house.

"Richard Fry"
> Still, a good earth ground and other means
> are desirable to protect your equipment from
> lightning transients...

Any 'Theory of Lightning' needs to be capable of including airplanes and their general success at lightning protection - obviously sans earth grounding. Typical airplanes get hits several times per year - often with no damage. 'Airplanes' is such an obvious one-word counter example to soooooo many arguments about the "necessity" (sic) earth grounding...

I'm glad you used the words "...and other means" and "desirable". You're not guilty.

Personally, I believe that a Faraday Cage (with appropriate entrance protection) would be far more effective than fiddling with (optional) earth grounds. Since most commercial buildings are metal or equivalent, this gives the 'lightning professional' a huge advantage over the amateur (in his wooden house). Much of what works for 'professional' lightning protection works ~because~ the commercial installation is in a metal building. This point needs to be acknowledged by those professing their experience while advising the amateur in his wooden house full of lengthy, low voltage signal wires. Having 20,000 amps surging (uh oh - 'surge' - that'll trigger off the 'w_tom' idiobot - sorry) down the ground wire is obviously going to cause 'sparks' in adjacent wires and cables and 'minor' equipment damage - even with a perfect earth ground.

Sorry, that statement cannot be correct. It would mean that the impedance you measure at the near end of a transmission line (terminated by some arbitrary load at the far end) would depend on the internal impedance of the device that's doing the measuring - and that is not true, either in transmission-line theory or in the real world. It is a function only of the line and the load.

Others can probably explain why the statement is also incorrect according to the concept of "forward and reflected power waves". Myself, I prefer avoid that concept completely, because it so easily leads into this kind of mess.

I just picked up some small egg insulators and have a question.

I had assumed that the wire went through the hole, was routed back in the groove to the far end of the insulator, and was twisted back on the standing part. The two loops overlap, as it were. However, the groove for the wire continues all around the egg, including the near end of the insulator opposite the standing part. This suggests some kind of fancy wire routing is expected.

How come they continue the groove all around? Do these sometimes get used with the insulator in tension and the loops not overlapping?

"Richard Fry"
> How....do you explain the "ghost image" .... TV

Sigh - moth + lamp (not you RF specifically, the newsgroup...).

LOOK - Discuss a simple step function (rising edge) - not RF. All of your disagreements about SWR and reflections will be revealed as silly semantics and the mixing up of the transient versus the steady state. A step function makes it so simple that there is no room for arguments.

There is NOTHING in the endless (and now repeating) discussion other than semantics and the above mention lack of discernment (initial transient versus steady state).

2774. How to measure SWR

Newsgroup: rec.radio.amateur.antenna
Date: 2004-09-04 14:08:53 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <chci9l$r10$1@titan.btinternet.com>
Source record: 89995

For those who have forgotten how or have never measured SWR.

Two separate voltage measurements are needed at two different places along
the line.
Slide the voltmeter along the line until a maximum is found.
Remember the reading, Vmax.
Slide the meter along the line again until a minimum is found.
Remember the reading, Vmin.
Before you forget, divide Vmax by Vmin.
You are left with a single number.
It has no dimensions.
It is the TRUE swr.

NOTE: In the above description and calculation there is no mention of Zo,
terminating impedance, source impedance, reflection coefficient, forward
power, reflected power, reflected volts, reflected current, Smith charts, or
conjugate matches. All these things are superflous to the determination. No
information other than the two voltage measurements is needed.

All other methods which purport to measure swr require injection of
additional information. And assumptions form an essential part of the
process. They can hardly be called swr measurements. Particularly when
they can indicate it on non-existent lines.

Richard Fry wrote:
"If the Model 43 is unable to make an accurate masuremnt of this, is that not due to reasons other than not having the right V/I ratio in its line section?"

Many details of desisn, construction, and application must be chosen and executed right to get accuracy, but the line impedance is essential.

Bird can adjust the current sample to exactly equal the voltage sample, both taken from the transmission line at any point. But it must work with a fixed voltage to current ratio. Bird chose 50 onms.

For a directional meter, it`s necessary to respond to one direction while rejecting the other. When power is applied to a line, the resulting current is is in phase with the volts. On reflection, the volts and amps in the reflected wave are 180 degrees out of phase. The phase difference of the reflected wave is used by Bird to distinguish it from the incident wave.

By selecting and adjusting for equal samples of volts and amps in the forward wave, their total is 2X that of either sample. But, the samples from the reflected wave, being equal but out of phase, cancel.

To get the value of the reflected power samples, it is only necessary to reverse the polarity of one of the samples. They are now in phase and the forward power samples are now out of phase and cancel.

If some other voltage to current ratio is used for the power samples than that of the design, the samples won`t be exactly equal and cancellation of the undesired direction does not work.

Best regards, Richard Harrison, KB5WZI

They can be called indirect (calculated) SWR measurements
and assumptions indeed do form an essential part of the
process. That's not at all unusual for indirect measurements.

> Particularly when they can indicate it on non-existent lines.

One of the assumptions is that a transmission line exists. If
a transmission line doesn't exist, the measurement conditional
assumptions are violated, and the actual values may not be
the desired or expected results. Happens all the time with
various measuring instruments.

Yes, that is a true observation, just as true as the one I made... so
now you have *two* different things to explain!

The so-called SWR meter is a steady-state instrument, so it always makes
sense to use that quicker, easier way of thinking. Since you're the one
who chooses to think of this particular situation in terms of multiple
reflections, any difficulties you encounter are entirely yours.

If you ever see a conflict between two different theories that explain
the same observed facts, then there's an error somewhere. If the
multiple-reflection theory is extrapolated to infinite time, so that it
calculates results for the steady state, it *must* give identical
results to the steady-state theory. But whenever the steady-state theory
can be used, it will always get you there much more quickly.

However, when you have finally done it your way, and accounted correctly for all the reflections and re-reflections, we can predict the outcome with complete confidence:

1. If you sum the successive reflections correctly to infinity, and calculate the V/I ratio and phase at the station end of the line, then the final result will be identical to the impedance given by the steady-state transmission-line theory. It has to be, because that single value is the reality.

2. Somewhere in your calculations, any value that you assume for the RF source impedance is going to cancel right out of your calculations. The correct mathematical result *must* be independent of that value - because, again, that's the reality.

If you have a directional wattmeter that *perfectly* senses and
displays the ratio of forward to reverse power, what difference does
the absolute power make? Hint: It doesn't.

But let's avoid going any further here. This has been argued about in
at least 10,000 other threads and has absolutely no bearing on Ian's
or my statements regarding the unimportance of source Z in the
discussion of measuring reflection coefficient.

In a laboratory environment, the source is usually well matched at the
system impedance. This is for convenience and improves accuracy only
because is takes less mathematical horsepower to remove the effects of
the "re-reflection" you speak of. This is particularly true when
highly mismatched loads are measured; and two of the most highly
mismatched loads are an open and a short, both of which are often used
as calibration standards.

Re-reflection exists and is actually an undesired thing in laboratory
measurements, primarily because most measurements are swept frequency
and the changing phase of the reflections is a pain in the ass.
Reflections are a source of *measurement error*. Removing the effects
is called *error correction* in the laboratory setting.

But I can tell you that if I calibrate a high-quality network analyzer
using a 50 ohm generator and then add a tee and second 50 ohm load to
the generator output, making it a 2:1 mismatched source, there will be
no significant change in the answer presented when typical
mismatches are measured.

Any differences represent measurement *error*, not measurement
reality. Reality is the interaction of the line and load and the

source plays *no* role.

This is correct. If you divide the formula for voltage, at any point on
a transmission line, by the formula for current, the generator impedance
cancels.

We agree on the subject of conflict resolution, but apparently not on
the location of the error.

> theory can be used, it will always get you there much more quickly.

This is true only to the extent that all the power ever generated by the
transmitter eventually either is radiated by the antenna or is dissipated by
losses somewhere.

For simplicity, let's assume a tx with a source impedance of zero ohms feeds
a lossless transmission line of uniform impedance throughout its length to a
mismatch at the far end. The mismatch reflects a percentage of the incident
power back down the line to the tx, and continues to do so as long as the
transmitter generates power. The tx will re-reflect the reflected power
back to the far end -- in this case all of the reflected power it ever sees,
in fact. To this easily-seen, real-world reality you agreed above ("Yes,
that is a true observation, ...").

The re-reflections combine with the power generated by the tx at that
instant to create a vector sum at the sample point used by the meter. The
typical tx meter is a frequency-domain device, and cannot by itself separate
the RF output of the transmitter from re-/reflections of it. That requires
a time-domain device. So the magnitude of the transmission line samples
driving the tx RF metering circuits during normal operation under these
conditions become a function of both the source impedance and the
load impedance.

The defense rests.

If you think it has good conductivity, do you wire your house with it?
Do you have a radial field using #38 wire in a one meter grid? Both
laughable propositions here, but those tears of mirth turn to the
dewey eyed mist of religious belief when Salt Water "conductivity" is
mentioned.

Sand is the least lossy ground beneath your feet, but how well does it
contribute to DX? Add some water and the loss skyrockets - and this
is called the boon of conductivity!

No, it is called the boon of reflectivity. The Z changed and power
CANNOT penetrate the interface. If you cannot get power into it,
there is nothing to conduct (and it is the molecular polarization and
relaxation moment that causes this, not conductivity).

The legends of mature spinsters are many with respect to the qualities
of ground - they even inspire useless software as crutches. I have
seen NO ONE here who can recommend it (much less admit they don't even
have a clue on what values would be appropriate for their own locale).
Hence most discussion is either faith-driven, speculation, or simple
hucksterism.

Right Ian, having equipment spread out over a wide area is an undesireable condition, but a reality for many operators. Running 3" wide or greater copper strapping in individual paths to one single bus "collector" is a challenge, but one worth trying. Equipment stacked or racked together could certainly be "grouped" and a common bonding strap run for each group to the SPG. But 20 linear feet of bus bar could have huge transient voltages developed across it from a nearby strike. As in a few hundred thousand volts between supposedly "grounded' equipment. Hence the importance of all equipment connecting to the same ground point, not via a long run of common bus bar to that ground point. Make your compromises according to your individual requirements and station layout. Just realize that in a nearby-by strike, lightning will find the weak points in any system and exploit that weakness to the fullest possibility. I experience numerous nearby strikes that probably raise the ground potential several hundred thousand volts, and expose my entire ground system to those voltages. If there were large potential differences between even bonded equipments in the station, deadly hazards would exist. It's all about choices, and we all have to make them.

Best regards,

Jack Painter

The fly in the ointment is a definition.

If a signal generator is sourcing 100 watts and 20 watts of reflected
power is being dissipated in a circulator load resistor, we say the
source is sourcing 100 watts and 20 watts of reflected power is being
dissipated in the circulator load resistor.

If the identical thing happens in a ham transmitter, we say that the
source is sourcing 80 watts, BY DEFINITION. What's wrong with this
picture? Ham transmitters NEVER re-reflect anything, by definition.

The reason that the source impedance doesn't enter into the forward/reflected
power values is that it has been defined out of any relationship to them. By
definition, there is zero power re-reflected from a ham transmitter NO MATTER
WHAT THE IMPEDANCE OF THE HAM TRANSMITTER MIGHT BE. Never mind that we can see
those reflections with our own eyes in TV ghosting. We must be crazy because
they have been defined out of existence. How dare we have the gall to observe
them!

This has been explained many times, to no avail.

So instead of one of us explaining it yet again, I suggest that you do the following experiment. It requires only a transmitter, one or two dummy loads, an SWR meter, and no more than five minutes of your time.

1. Connect the transmitter to either a dummy load or an antenna through the SWR meter and measure the SWR.

2. Connect the transmitter in parallel with a dummy load by using a tee connector. Connect this parallel combination to the input of the SWR meter, and the output of the SWR meter to the same load as before (dummy load or antenna).

Do you see any change in the SWR?

If you don't, then something is wrong with your theory -- since the source impedance is clearly different for the two measurements --, and you should take the effort of resolving it with your recent observations.

Let me suggest an additional exercise for Richard and anyone else that believes that source impedance affects the SWR.

Those of us who believe otherwise can easily calculate the SWR which will exist on a line, and the SWR that will be read by an SWR meter at any point in a system, by knowing simply the line length and impedance and the load impedance. We don't require knowledge of the source impedance. The equations we use can be found in numerous places, and these have been used for over a century to design working systems.

You must use other equations to predict SWR -- equations which include source impedance. It would be very interesting to see those equations. Your equations and ours will predict different results from the simple test I proposed. So if you'll show us the equation you use to calculate SWR which includes source impedance, it'll be easy to see whether it's correct or not.

Richard Clark wrote:
> I see you have yet to respond to this very matter attended to quite at
> length by Chipman.

I have recently realized that those terms in Chipman's equations are
interference terms. EM wave interference is not understood very well
by RF people although it is understood very well by optics people.

For instance, the superposing of two coherent voltages in a Z0
environment is well known.

Vtot = V1 + V2 (assume V1 and V2 are in phase)

Squaring both sides and dividing by Z0 yields the power.

Vtot^2/Z0 = (V1+V2)^2/Z0

Vtot^2/Z0 = V1^2/Z0 + V2^2/Z0 + (2*V1*V2)/Z0

Note that the first term to the right of the equals sign is the
power associated with the V1 wave and the second term is the
power associated with the V2 wave. The third term is the
interference term. If V1 and V2 are in phase, the third term
will be constructive interference.

If the phase angle between V1 and V2 is less than 90 degrees,
the interference is constructive, i.e. cos(theta) is positive.

If V1 and F2 were 180 degrees out of phase, the interference
would be destructive.

If the phase angle between V1 and V2 is between 90 degrees and
180 degrees, the interference is destructive, i.e. cos(theta)
is negative.

Interference is the reason for those extra terms in Chipman's
equations. It always happens when the sum of two voltages
are squared to get the power.

Just one sec, please. I didn't say that the true SWR connected to the tx output connector was affected. I said that the RF power measured at the sample point(s) in the transmitter can be affected by the source and load impedances of the tx, for the reasons stated.

The true load SWR does not change under these conditions, but it cannot then be determined by such a meter. Attempting to do so will yield some value, but it will be wrong.

It's been many years since my EM theory days in school, but I seem to remember being taught that the way surfaces reflect EM waves is by being excited by the impinging wave and then re-radiating due to the current flow caused by the arriving wave. This would require the surface to be a good conductor to be a good reflector.

Good Sir,

A bit of a disconnect appears to occur in the above two clips between your stated desire to avoid bad manners, and the consistency with which you do it. Most people are more willing to entertain another's point of view if such is given without hostility and intimidation.

With all due respect,

RF

Walt,

I hope people are listening to what you are saying. I built up a Bruene meter in SWCAD using 0% tolerance components and other ideal parts. Works exactly like Bird claims their meter does, except that the error only depends on the PC floating point arithmetic. Transmission line or not makes no difference. BTW, it is kind of neat to see the directional coupler properties, by driving the two sides with different signals, and then being able to separate them.

Dear Ken: The wire loops overlap. The insulator is in compression not
tension. If the insulator breaks, the wire is still, sort of, supported.
The "egg" insulators that I have used did not have a groove that went
all of the way around.
For reference: about how large are your insulators?

From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10jkdp96ap1u960@corp.supernews.com>
Source record: 89922

Sorry, I must have misinterpreted your earlier posting.

But we seem to now have a "true SWR" as opposed to some other kind of SWR. And "true SWR connected to the tx output" doesn't have any meaning at all to me. I also have no idea of what "sample points within the transmitter" might be. So let me explain what I (and virtually all published literature) mean by SWR.

If we connect a transmitter to an SWR meter, and then to a long piece of lossless cable with the same Z0 as the SWR meter, and finally to a load, the SWR meter reading will be the same as the VSWR on the cable, i.e., the ratio of maximum to minimum voltages on the line. This ratio of voltages is, by definition, the VSWR -- which equals the ISWR, and is often referred to simply as SWR.

If we measure or calculate the impedance seen looking into the line, then disconnect the line from the SWR meter and replace it and the load with lumped elements of the same impedance, the SWR meter reading won't change(*).

Now, I can calculate the what the SWR meter reading will be under this condition also. In both cases, the source impedance won't affect the SWR meter reading, the positions or relative magnitudes of the maximum and minimum voltages on the line, or the voltage or current within the SWR meter line section. (This last condition assumes that the net power delivered by the source stays the same; otherwise, the ratio of voltage to current, and their phase angles, stay constant, regardless of the power delivered.)

I have no idea how all this relates to your "true SWR". But do you agree with what I've said above? If not, I'll describe a couple of simple experiments which will test it against any alternative view you might propose.

(*) We can also replace them with a load at the end of a line of different Z0. As long as we choose the load Z and the line length to make the impedance seen at the line input the same as before, the SWR meter will read the same as before -- even though it no longer equals the actual VSWR on the transmission line. The SWR meter is really indicating the impedance seen looking into the line, not in this case the actual line VSWR. (That's the essence of Reg's objection to the SWR meter designation. Of course, if I connect my ammeter across a resistor, it's not measuring the current through the resistor, either.)

==========

Water can be kept out of slotted cables by the ship's radio operator who never has anything else to do. We used to toss him overboard with a ladle and pump. On occasions we used the ship's doctor when he wasn't propping up the bar boozing duty-free scotch.

Didn't have to swim anywhere. The propagation velocity is so low at ELF in sea water it is necessary only to sit on a stool in a diving suit and wait for the max's and min's to pass by.

>mismatches are measured.
>

Hi Wes,

To offer some numbers in regard to the Mismatch Uncertainty to show
the insignificance in relation to common experience.

A 2:1 mismatched source feeding a 2:1 mismatched load injects (by the
graph) about +25% to -20% range of uncertainty. To amateur standards
of measurement, about the best they could do anyway, and generally
accepted with complacency as "perfect."

There is a very simple relation for finding this range of uncertainty:

1 / (1 ï¿½ |G1|ï¿½|G2|)ï¿½
where
|G| = (SWR - 1) / (SWR +1)
or for both SWRs at 2:1
|G| = 0.333
and
1 / (1+ 0.111)ï¿½ = 0.81
and
1 / (1 - 0.111)ï¿½ = 1.27

If we repeat this exercise with more radical 3:1 mismatches on either
side of the SWR meter, then the range of uncertainty becomes:
1 / (1+ 0.25)ï¿½ = 0.64
and
1 / (1 - 0.25)ï¿½ = 1.78
or roughly -40% to + 80% error.

Now, given few (if any) amateur transmitters (of the transistor
persuasion) exhibit even as much as 2:1 mismatch at their port to a 50
Ohm load; then it is reasonable to presume the range of error is not
as outrageous (insignificant to pedestrian accuracy).

However (the part I enjoy), for those who persist in maintaining their
transmitters (of the transistor persuasion) do NOT exhibit anything
close to 50 Ohms; then they have no business discussing power levels

into mismatches except as an expression of fantasy.

To date in this matter, I have yet to see any concrete value of source Z offered from those of the NOT 50 Ohms camp. Further, I have yet to see any of them offer any experimental confirmation of their assertion (made rather simple by the exhibition of uncertainty). I have offered several means to accomplish this confirmation. I have even offered data from actual tests that exhibits this confirmation. I have even offered references that speak directly to this uncertainty. But I do admit from one retort "you are not going to change my mind" that such impeccable logic will always prevail. :-)

2804. horizontally polarized antenna over ground plane

Newsgroup: rec.radio.amateur.antenna
Date: 2004-09-04 21:57:09 UTC
From: Andrey <a8421@intergate.bc.ca>
Message-ID: <10jkehojcaol9bd@corp.supernews.com>
Source record: 89925

Greetings to all the antenna experts here!

I want to create horizontally polarized antenna, low profile, located above large ground plane. And I need it to be omnidirectional (sort of) and have sufficient gain in horizontal plane.

My frequency of interest is 900 MHz. The ground plane is a roof of a car.

I tried loops, from 50 to 300 mm diameter, radiation goes up if I mount it above the ground plane.

Any ideas?

Thank you,

Andrey

Hi OM,

Replace any low Ohm plane with a hi Ohm plane. No conduction issues
(or even vastly worse than salt water) there at all, same reflection -
n'est pas?

For those who've studied freshman Physics, this is called Snell's Law.

My "true SWR" term is used is an attempt to differentiate between the SWR of the antenna system, and the inaccuracies associated with trying to measure it with devices that cannot isolate the incident power in the system from internal reflections of that power. For the conditions and reasoning outlined in my earlier posts in this thread, and even though the system SWR is a constant -- the normal SWR meter used in/with an operating transmitter working into a mismatched load won't have the ability to give strictly accurate measurement of that SWR. That is all I'm saying.

> I also have no idea of what "sample points within the
> transmitter" might be.

In broadcast gear, these are the directional couplers whose pickup probes are inserted transversely into the coaxial line between the harmonic filter output and the tx output connector. I haven't been a licensed ham for over 40 years (when I went into the broadcast field), but I expect some ham txs might have the same setup. Otherwise it could be a Model 43 or the like inserted between the output connector of the ham tx and the transmission line to the antenna.

I hope this is understandable now.

>
>The re-reflections combine with the power generated by the tx at that
>instant to create a vector sum at the sample point used by the meter.

There's the error: you can't "combine... power" in that way. You can only create vector sums of voltage; and separately, vector sums of current.

To make the multiple-reflection theory work correctly, you have to do two separate vector sums at output port of the transmitter. First you add all the voltage vectors: the 1st (original) forward, the 1st reflected, the 2nd forward (re-reflected), 2nd reflected... and so on, summed to infinity to give the correct result for the steady state. Then you do the exactly same for all the forward and reflected current vectors.

In order to account for reflection from the transmitter, you have to assume some value of source impedance. Any value will do, for reasons we'll see in a moment.

Now you can calculate two things: the vector ratio, which is the complex impedance that the transmitter sees as a load; and the scalar product, which is the power the transmitter can deliver into that load.

If you vary the source impedance of the transmitter, it will change all the summed voltage vectors and all the summed current vectors - but each voltage term in the sum will be changed by exactly the same factor as its corresponding current term. Certainly the product (the output power) will change, but the ratio (the load impedance) will not.

So, when correctly worked out, the load impedance is *not* a function of the transmitter output impedance or the output power. Likewise, the indication of the SWR meter is not a function of either the transmitter output impedance or the output power - this last one being a well-known fact.

Please see the following. In the quote there, note the text starting "The transmitter's output source impedance must be low...", and the following sentences.

+ + +

Below is a quote from a paper titled "A Study of RF Intermodulation Between FM Broadcast Transmitters Sharing Filterplexed or Co-located Antenna Systems," by Geoffrey Mendenhall. Mendenhall is a registered professional engineer, and now a VP for Harris Broadcast Division in Mason, OH. He is responsible for the engineering research and design of the entire broadcast transmitter product line for Harris: AM, FM & TV. Harris is the world's largest supplier of broadcast transmitters.

This paper and quote has to be read here with some interpretation, because it is an analysis of what happens when an in-band signal from one transmitter is coupled into another transmitter when their antennas are close together and/or when adequate filtering of the external signal is not provided. But it is strictly applicable also for single tx and antenna systems, where an antenna mismatch produces reflections back toward the transmitter. In this case the "interfering signal" is not external, but a reflection of the incident power of that tx.

QUOTE: Output return loss is a measure of the interfering signal that is coupled into the output circuit versus the amount that is reflected back from the output circuit without interacting with the non-linear device. To understand this concept more clearly, we must remember that although the output circuit of the transmitter is designed to work into a fifty ohm load, the output source impedance of the transmitter is not fifty ohms. If the source impedance were equal to the fifty ohm line impedance, half of the transmitter's output power would be dissipated in its internal output source impedance. The transmitter's output source impedance must be low compared to the load impedance in order to achieve good efficiency. The transmitter therefore looks like a voltage source driving a fifty ohm load. While the transmission line is correctly terminated looking toward the antenna (high return loss), the transmission line is greatly mismatched looking toward the output circuit of the transmitter (low return loss). This means that power coming out of the transmitter is completely absorbed by the load while interfering signals fed into the transmitter are almost completely reflected by the output circuit. END QUOTE

The transmitter topology in this study was a single PA tube operating Class C. For these designs, an on-carrier return loss value of 2 dB or less is rather common. At 2 dB the reflection coefficient is over 79%.

PAs comprised of multiple devices combined by balanced methods (e.g. 3dB hybrids, Wilkinsons) can provide a source impedance closer to 50 ohms (higher return loss). In these cases, power that is reflected off the load and NOT re-reflected by the tx mostly is dissipated in resistive networks in the PA combiner. However these networks do not provide a load for the forward power from the tx, only for power reflected by the output termination.

In your last posting, you said,

> Just one sec, please. I didn't say that the true SWR connected to the
> tx output connector was affected. I said that the RF power measured
> at the sample point(s) in the transmitter can be affected by the
> source and load impedances of the tx, for the reasons stated.

So replacing "sample point(s) in the transmitter" with "Model 43 or the
like inserted between the output connector of the ham tx and the
transmission line to the antenna", you've said that the RF power
measured by the (model 43) SWR meter can be affected by the source
impedance of the transmitter.

Obviously, if we have a voltage or current source of fixed value and change the source impedance, the power delivered by the source changes, and any means of measuring the power at the source, load, or in between should show that change. That follows from elementary circuit theory, and doesn't require any consideration or knowledge of transmission lines, waves, or SWR. On the model 43, both the "forward" and "reverse" powers will change, but by the same fraction. Perhaps that's what you mean. But if you mean that the SWR reading or the ratio of "forward" to "reverse" power changes as a result of changing the source impedance, that's easily shown to be false by the simple experiment I proposed.

> I hope this is understandable now.
>
Almost, but not quite.

Ah Punchinello!

Clowning as ever, I see. A seque from the world's worst conductor to
the world's worst dielectric? This is the price of superlatives in
place of engineering specifics. Whatsamatta, did you defrock your
saint Kelvin?

What is the loss tangent of the mud in your garden Reggie? ;-)

Well, anticipating your typical loss for a response, and for others, a
nice round value of 1 is easily within rough accuracy. Corrections
(not speculations) are encouraged. Be specific.

W1MCE replies:

I have used a 1/2 inch copper pipe mounted along the back edge of the table[s] holding my station equipment.

The case of each piece of equipment is connected directly to the copper pipe using 1 inch braided strap about 6 to 12 inches long depending on equipment size. This pipe provides an equipotential plane for all my equipment. [Another method would be to install a thin copper sheath on top of your desk/tables and connect directly to it for the equipotential plane.]

Now, how to connect the equipotential plane to brown dirt [earth] is the next issue. You are correct that it is desirable to keep this 'non-resonant' on the bands you operate. There are two issues here that need to be addressed. First, if you are close to the earth ground then a simple #6 AWG wire to a ground rod is adequate. Second, if you are higher than 1/4 wavelength at the highest frequency of interest use two #6 AWG wires OF DIFFERENT LENGTHS, not harmonically related, connected to the ground rod. The different lengths assure that the equivalent connection is NOT RESONANT.

In very fortunate cases an additional station ground is not required! Believe it or not! ... My station is located on the ground floor in the family [my] TV room right under the electrical distribution panel. My 120 VAC line comes directly from the service entrance through about 3 feet of wire. The 240 VAC for my amplifier comes directly from the service entrance through 4 feet of wire. The service box is 'earthed' by a NEC compliant connection. My connections to the service box are therefore very short.

A major point of caution is required. The NEC requires ONLY ONE ground connection. Multiple ground connections introduce VERY SERIOUS ground loops that may violate the NEC criteria. This opens a VERY LARGE loop hole in your home owner's insurance policy. If you are adding a second

earth [ground] connection at your station use an isolation transformer to break up the ground loops in the basic 120 VAC connection. Consult with an electrician regarding your local and NEC codes.

It is noted that station grounding and antenna counterpoise construction are two different things. I am not addressing the counterpoise issue.

One DONT see listed is the (actually there are 2 of em!) Over-the Horizion radar antennas constructed about 30 miles south of Tule Lake , Ca, and looks to be about 20 MHz freq wise! Tho shut down, these are still mothballed, and are about 3/4 MILE LONG array of Rohn tower sections, every (again, as observed, not measured-- Wackenhut the security outfit, would NOT be amused if CLOSELY inspected!) , spaced about every 15-20 feet, this on a surface of chicken wire/ fenceing material , on the ground surface, about 800 - 1000 foot deep, and, a backstop, again guetimate, , about 10-15 foot high! aimed at Russia! Would be interesting to try one of these out, sometime (Work all Oblisks, QRP??) sometime, but, might not have the military very happy with you !! Jim NN7K

2814. Re: Egg insulators

The loops are supposed to overlap!!! In the event of a broken insulator
the antenna is still suspended and not on the ground!!

For a successful installation use wire for the antenna [of course] and
antenna rope for the connection to the supporting end. If the insulator
breaks, your antenna is still 100% operable.
